layer of the superficial mucosa were sliced off. These ulcers may be very large. The adjoining region may be hemorrhagic and the whole gastric mucosa may show hyperemia. The ulcers may occur anywhere in the stomach, as often on the posterior aspect as on the lesser curvature. The average pathologist would recognize such as an atypical ulcer not belonging to the common and classic gastro-duodenal type of ulceration which occurs on the lesser curvature with induration and thrombosis. Yet the anatomical diagnosis of these nephritic ulcers would read as follows: 1. "Nephritis. 2. Hypertension. 3. Peptic ulcer," and unless one recognized the proper group into which this ulcer belongs one would record in the permanent literature a psychogenic (chronic) ulcer associated with hypertension and nephritis. Only in a very narrow sense is this true, surely in no way to throw light on its real etiology.

The patient suffered with nephritis and hypertension for years and gave little sign of gastro-intestinal upset. As a terminal and probably toxic development in the long course of his illness he developed an erosion of the stomach. This gastric lesion is as incidental to nephritis as a bed sore is to any patient with a long bed-confining illness, and has as much reversible relationship. The ulcer in the gastro-intestinal, respiratory or urinary tracts played no major *rôle* in the disease itself, at least not so far as the underlying pathogenesis of nephritis is concerned. It may hasten the death of the patient through internal hemorrhage but this is accidental and not relevant to the disease or its elucidation. Similarly, a patient with Raynaud's disease may develope lymphangitis in one of the phalangeal ulcerations and die therefrom. But the lymphangitis would have had nothing to do with the etiology of Raynaud's disease. Is it possible that the great discrepancy in the incidence of hypertension in the psychogenic (chronic gastro-intestinal) ulcers is due to such an error? The actual percentage as given by different authorities varies from 2% to 14%. This is entirely too great a difference in so clear-cut a disease of a finding so easily determinable. This is not a mere academic issue for two reasons. In the first place, many men claim that hypertension plays a *rôle* in the etiology of psychogenic ulcer.* Secondly, those of us who claim it is a neurocirculatory disease are keenly interested in interpreting the mechanism of the autonomic system that limits its vascular constricting effects to the stomach and duodenum and spares the peripheral vascular bed.

We may now cite a reported case in the literature which illustrates the point first mentioned, namely, the danger of attributing to psychogenic ulcer specific findings that in reality belong to other types of gastro-duodenal ulceration.

Case I. Colored male, 41 years of age, ill for 8 months with shortness of breath, nausea, vomiting and indefinite soreness in abdomen. There was a marked loss of weight and swelling of ankles. History of a chancre and of gonorrhea. BP 160 60. Heart was enlarged, and there were systolic and diastolic bruits. Both lung bases showed impaired resonance and rales; the liver was enlarged. *At autopsy*, at the Cook County Hospital in Chicago, Dr. Jaffe found multiple ulcers on the greater curvature "irregular in shape and atypical in location—deep with soft edges and apparently of short duration and their multiplicity and irregularity indicate that they developed from hemorrhagic erosions." The anatomical diagnosis gave no clue of any specific disease (32).

This patient obviously did not belong to the psychogenic type of ulcer. Dr. Jaffe, the pathologist, was quick to recognize this and to mention its atypical characteristics and its different etiology as due to hemorrhagic erosions. The findings if *loosely* grouped would be incorrectly classified as those of a psychogenic ulcer showing the following five points: 1. The ulcer occurred in a Negro. 2. Occurred along the greater curvature. 3. Was associated with hypertension. 4. An organic murmur was present. 5. The histopathology showed: a. Multiple ulcers. b. Soft edges and no induration.

The inclusion of these findings as typical of a patient with psychogenic ulcer would be incorrect statistical evidence. *Not one of these findings is ordinarily associated with a psychogenic ulcer.* It is not common in the Negro, does not occur along the greater curvature of the stomach, is not associated with hypertension or organic heart murmur: the ulcer is not generally multiple and its edges are not soft. The literature is full of these ulcers that are secondary to other diseases especially nephritis (9). These hemorrhagic erosions are often *bizarre* in their appearance and very atypical in their location. Some are very large as the following case demonstrates:

Case II. Reported by Crohn.

"The ulcer eroded nearly the entire posterior wall of the stomach so that the palm of the hand laid on it covered it with difficulty" (29).

The symptoms and signs of these ulcers must not be confused with those of the psychogenic type. Continued scrutiny would make the clinical picture of the psychogenic ulcer so clear and sharply outlined that etiological conclusions would force themselves upon us in logical sequence.

Another source of error in assigning wrong symptoms and signs to the psychogenic ulcer is an incorrect diagnosis. Smithies has called attention to this source of error and quotes William J. Mayo (33), "a patient may have been treated medically for a long time and yet the patient may have had no ulcer." Deaver (41), going still further and probably a little to the extreme says that not half the patients undergoing medical treatment for ulcer actually were subjects of ulcer.

It is also urged that the selection of the ulcer patient for statistical data be made from the younger age groups. Ulcer is a disease of youth and early middle life and the true picture should be sought here, rather than in advanced years when findings are contaminated by degenerative diseases.*

Even the X-ray is not infallible. Some defective duodenal bulbs that are diagnosed as ulcers are found to be something else at autopsy or at the operating table (33, 34).

c. Burns. These ulcers, often called "Curling ulcers" in honor of Curling (39) who described them in 1842 in a series of four of his own duodenal ulcers, may be found in cases after severe burns. They are most often found in the first portion of the duodenum

It is suggested that blood pressure readings be studied in a series of ulcer cases in which the age limit is from 35 to 45. If only the [illegible] type is selected, the incidence of hypertension [illegible]

*One must differentiate here between ulcer presence as diagnosed by the clinician and ulcer incidence as recorded by the surgeon or the pathologist. *Editor.*

as pointed out by Moynihan and since this is also the site of most psychogenic ulcers it was thought wise to make a separate group of them on the basis of this site selectivity. In most cases there is also to be found hemorrhage into the suprarenals and this relationship has offered interesting speculation. In the experimental animal partial destruction of the suprarenals results in duodenal and jejunal lesions in a fairly large percentage of cases (40).

d. Brain Trauma. Cushing in 1932 summarized the evidence of the production of gastro-duodenal ulcer following surgery, neoplasms and experimental irritation of the interbrain. Fulton, Watts, Hoff and Sheehan (35, 47), have demonstrated that gastric erosion may be produced following experimental lesions of the hypothalamus in monkeys. This work is of the greatest significance not only in establishing the definite relationship between brain lesions and gastro-duodenal ulcers but also in establishing their most likely location in the diencephalon which is being looked upon more and more as the seat of emotions. It is this primitive brain which doubtless exercises most of the involuntary control of visceral function through autonomic control. Many pathways connect the diencephalon with the cerebrum.

e. Follicular Ulcer. This is a very rare ulcer occurring chiefly in infants. It involves the lymphoid tissue generally and particularly that of the stomach, and is probably on an infectious basis.

CONCLUSIONS

It is claimed that there has been considerable confusion of the different types of gastro-duodenal ulcers one with another. For clarification a classification of these various types of ulcers is presented. A major division is made into "Direct" and "Indirect" causes. The *Direct* ulcers constitute but a small proportion of all gastro-duodenal lesions and includes those which have their origin in the wall of the stomach or duodenum. The *Indirect* group, comprising by far the largest number of ulcers seen, includes those whose causes, such as psychic, toxic, bacterial, etc., come from outside the gastro-duodenal wall. They may be the primary manifestation of a systemic condition as in the case of psychogenic ulcer, or they may be very incidental to it as in the case of the hemorrhagic erosions. This latter group is the type most frequently confused with the true psychogenic ulcer. In order to have a clearer understanding of the psychogenic ulcer (chronic ulcer) so we may better be able to arrive at its etiology the factual data must be agreed upon. We have as yet not reached any unanimity of opinion about the objective data of chronic ulcer. Is there an ulcer type of individual—a "race" of white men that practically alone is susceptable to the disease?* Is there a definite constitutional build and personality type amongst these patients? Is the pathology of the ulcer distinctive? Is it different from other ulcers in the gastro-intestinal tract? These questions strike at the very root of the whole ulcer problem. Our knowledge of any disease entity is built up painstakingly by recording the subjective and objective findings associated with it. We then try to assign some causative factor that would duplicate these findings. If our objective data are in error our interpretation of them in light of etiology must be faulty.

If we were to assign correct findings to the proper ulcer types we should then have no difficulty in establishing the clear cut and true picture of the psychogenic ulcer patient. It is claimed that the following would constitute the *"irreducible minimum"* findings in by far the largest per cent of cases: The history is of years' standing, of seasonal exacerbations and remissions, the classic story is upper abdominal distress after food which in turn is relieved by food. The build of the patient in over 95% of the cases is long and thin. There are ten times as many males as females. There is a definite personality pattern of emotional instability associated with worry and fear. The histopathology is a sharply cut out and clean ulcer occurring in the first portion of the duodenum and along the lesser curvature. The adjoining mucosa is normal, with thrombosis and induration with maximum involvement near the serosa. The X-ray shows hypertonicity of stomach and duodenum. There is hyperacidity. Nearly all the other findings are normal including blood pressure.

If we agreed upon these findings the etiology would become much more apparent.

SUMMARY

1. A classification of gastro-duodenal ulcers on an etiological and clinical basis is presented.

2. There is discussion of the limitations of histopathology in the elucidation of the chronic ulcer and other psychogenic diseases. For that reason the pathological picture of the ulcer itself plays a minor role in this classification.

3. Evidence is advanced to show the inadequacy of the term "peptic" as descriptive of gastro-duodenal ulcers. The term "chronic" is shown to be loose and without any specific connotation.

4. The term "psychogenic" is suggested as a substitute because it is descriptive of the causal relationship of the disease.

5. Malignant transformation does not occur in a benign psychogenic ulcer.

6. Traumatic ulcer is classified as brought about by direct causes and therefore could not result in a psychogenic (chronic) ulcer.

7. The subjective, physical and laboratory findings of hemorrhagic erosions should not be included in statistical studies of the psychogenic type of ulcer.

*In a comparative study of disease, morphology and emotional response of the Negro race in the U. S., the most deeply pigmented members should be selected for any adequate approach to true racial representation. Mulattoes, quadroons and octoroons do not represent the Negro.

There is full anthropological and social evidence to show that the Negro is a more primitive member of the human race. A good summary is "Human History," by G. Elliot Smith.

New Experiences with Simmonds' Disease

By

KARL HERMAN, M.D.
SUBOTICA, JUGOSLAVIA

TEN or twelve years ago Simmonds' disease was very rarely mentioned in medical literature. Latterly, however, articles on this subject have appeared more frequently, particularly in German, French and English publications. In German literature the works of the Hamburg researcher Reye helped very largely to propagate popular knowledge as to the nature of this disease. Since then, however, many other authors (Grafe, Steinitz, Lightwitz, Redlich, Frazier, Wildner, etc.) have communicated similar cases. I myself have come in contact with two cases, a description of which has already been given, while in the last three years I have succeeded in discovering three recent cases which I should like to communicate here.

I. Woman, aged 61, had been ill for about a year. Main symptoms: intense itching and serious insomnia. Bodily strength markedly declining; loss of appetite, low spirits, suicidal tendencies. Had lost about 18 lbs. in weight in one year. According to previous medical opinion, the case was one of nervous debility; in hospital Addison's disease was suspected.

St. pr.: Face light brownish in color, with wrinkled withered skin and sad expression; great general debility; complete absence of hair in armpits. Moderate degree of anaemia. Roentgen investigation of stomach and intestines: negative. Thoracic organs sella turcica, blood sugar, blood pressure: normal. The increasing adynamia and apathy, lack of appetite, sleeplessness and the absence of hair in the armpits were signs that this was not a case of ordinary senile pruritus. For this reason I suspected a rudimentary form of Simmonds' disease and therefore prescribed hypophysis (anterior lobe) hormone. The effect was remarkable: after one week the patient already felt better, her muscular strength increased, and even walking did not trouble her.

The patient was under treatment for about 4 months. At first she was given 10 injections of the Prehormon preparation produced by the Promonta Factory and when the supply ran out I gave her temporarily, for lack of anything better and without her knowledge, injections of arsenic. After the third arsenic injection the patient asked me whether I should not have changed the treatment, for she again felt light-headed and walked unsteadily. After a short time she was again given Prolan per os and in the form of injections. When the supply of Prolan was exhausted, Richter's Glanduantin was administered and, after that, Horpan. The effect was excellent, while no difference was to be found between the various hormone preparations. After four months' treatment the

Submitted March 16, 1936.

Fig. 1. Case I—Before treatment.

patient was completely cured. Her weight had increased by over 17 lbs., her facial features were also altered and the skin looked fresh. The shedding had entirely ceased; whereas previously an X-ray treatment had to be given every six months, no irritation whatsoever has occurred for the past two years. The patient is completely fit for work; she is on her feet all day and does her work perfectly. It was not easy to make a diagnosis in this case. While local symptoms were completely absent, the development of prepotent general cachexia permitted the deduction that Simmonds' disease might possibly be present. The success of the specific treatment confirmed the diagnosis in every respect (Figs. 1 and 2).

II. Girl, aged 20. Able to walk only when supported by two persons. The mother stated that the patient had had no appetite for about nine months and was losing weight. The parents believed that as the result of a psychic trauma their daughter had lost the desire to live. She never had fever. Disordered sleep; examination of the bowels only after taking a purgative.

St. pr.: Greatly emaciated; height 5 ft. 7 in., weight 73 lbs., heavily-built (normal weight 121 lbs). Skin pale and flaccid, tongue slightly coated, eyes glazed. The skull when examined by touch and also when X-rayed was found to be normal. Heart, lungs, aorta, diaphragm: normal. Stomach normally curved and ptotic. Peristalsis was rather weak, gastric digestion took about 5 hours, the duodenum was quite normal. After 24 hours the colon was completely filled by the contrast clyster. The transverse colon was highly ptotic, the cecum normal; the skiagrams of the kidney and suprarenal capsule showed no calcified areas (Addison). No parasite or concealed haemorrhage was to be found in the stools; urine and blood pressure were normal. Blood sugar 130, Sahli 75, number of erythrocytes 3,000,000, leucocytes 6,700, normally distributed; blood gravitation velocity normal. No pathological changes were observed in the sensory organs or in the nervous system; sight, hearing and reflexes good.

In view of the disparity between the local and general symptoms I thought it might be a case of endocrine cachexia, especially of Simmonds' or Addison's disease. The relatively large amount of blood sugar was opposed to Addison's disease, although in Simmonds' disease also the quantity of blood sugar is usually low. A high blood-sugar factor, however, tends to disprove the presence of Addison's disease. As a precautionary measure I administered both Prolan and Cortigen, for whichever of these diseases was present one of these two remedies would have to take effect. The efficacy of Richter's Cortigen in saving life I had already proved in the case of one of my patients suffering from Addison's disease—a case which I described in the American Journal "Endocrinology" (1931). The excellent effect of Prolan was known to me not only from the literature concerned but also from personal observation. After eight days I discontinued the administration of Cortigen. In addition to the blood-sugar factor, the patient's apathetic attitude also indicated that this was more likely to be a case of Simmonds' disease. For another three weeks the patient continued to lose weight. Then the wasting process was checked, and in the fourth week a slight increase in bodily weight was recorded. After two months' treatment the patient was discharged, by which time her weight had increased by nearly 8 lbs. Meanwhile her strength visibly increased, her appetite improved, she slept well and was already able to walk without assistance. The face filled out, the skin lost its previous alabaster pallor, vitality and enjoyment returned. For a considerable time still the hormone treatment was continued at home by the family doctor, and then definitely stopped. One year later the patient was so strong and healthy that she was chosen as representative by a sports association of her home town—a distinction which is rarely accorded to persons suffering from Simmonds' disease (Figs. 3, 4 and 5).

III. Man, aged 45. Had been ill for three years, and during the previous seven months had become markedly weak and pale, while losing appetite and weight. During the same period he had become hard of hearing in the left ear. Most of the symptoms were associated with the stomach: gastric oppression and a feeling of fullness, also occasionally pain. Marked perspiration ½-1 hour after food. Was totally unfit for work; impotency had appeared about six months previously.

St. pr.: Pallid skin, tired expression, hollow-eyed; slow movements like those of an old man. Hair on scalp and body normal, tongue slightly coated, tonsils normal, pupils reacted promptly to light and accommodation. Blood pressure according to Riva-Rocci's test 90. Results of X-ray examination: heart normal, aorta regular. On medial right, below the clavicle, a primary complex of the size of a pea. In the apex of both lungs small calcified patches hardly as big as a lentil. Diaphragm free, stomach normally curved, its position and size normal; increased peristalsis, loiliew of usual shape, remaining portions of

Fig. 2. Case I—After treatment.

Fig. 3. Case II—Cachexia high grade—Before treatment.

duodenum also normal. Evacuation normal, the stomach empty in five hours, the small intestine filled, the colon showing incipient filling. After seven hours, the position was unchanged. After 24 hours the filling had reached only the middle of the transverse colon. The cause of the delay was the caecum ascendens, situated far down in the true pelvis. By means of X-rays and a contrast clyster it was possible to observe clearly the colon throughout its length, and it proved to be normal. Test breakfast results: free hydrochloric acid 20, total acidity 40, blood negative. The skiagram of the suprarenal capsules showed no abnormal, calcified patches. Wassermann reaction negative, blood sugar 123. Blood picture: number of erythrocytes 3,900,000, leucocytes 7,000, Sahli's test 75; rod-nuclear cells 3%, segmented 72%, lymphocytes 24%, monocytes 1%. The patient was given Preloban per os, as also Prolan and Cortigen in the form of injections. In two days the effect was already apparent. The patient felt stronger and was better able to walk, his bearing became more confident and his appetite returned. In the first week he gained over 3 lbs. Moveover, the improvement has been continuous, the increase in bodily weight being now about 10 lbs. (Figs. 6 and 7).

What is the real nature of this disease? A hypofunction of the anterior lobe of the hypophysis? It may or may not be accompanied by morphological changes. Reye observed Simmonds' disease in women only, and among my own patients there were four women and only one man. Reye considers that Simmonds' disease is present only in cases where an idiopathic primary change has occurred in the anterior lobe and not in those where this lobe is being destroyed by syphilitic gummata, a tubercle, a tumor or meningitis. He is of the opinion that the idiopathic decay of the specific tissue is the essence of Simmonds' disease. This conception, therefore, visualizes a change in the anterior lobe such as that observed in the liver in cases of cirrhosis, in the kidneys in cases of chronic nephritis, and in the heart when myofibrosis is present. According to Reye, there are also lighter cases in which only a part of the gland tissue is diseased. This is highly probable, for the patients usually recover after a 2-3 months' treatment and keep well even when they receive no further treatment perhaps for years. This can only be attributed to the fact that the endogenous hormone production has begun anew.

In the symptomatology of this disease many symptoms have been described, but, unfortunately, these are not always reliable guides. It would hardly be possible to find a symptom which could only be attributed to disease of the anterior lobe of the pituitary body. From the variety of symptoms one may diagnose now a thyroid or suprarenal disorder, now a derangement of the genital glands. How may these ailments be differentiated? A myxoedematous patient is fat, or at least does not lose weight, whereas a person suffering from Simmonds' disease loses weight continuously and the flesh may waste away down to the very bone. The tongue of the former is thick, while that of the latter is normal or thin. The best method of differentiation, however, is *ex juvantibus*. A person suffering from Simmonds' disease, however myxoedematous he may appear, is not restored to health by thyroid hormone, but is easily cured by hypophysis hormone. Menstruation ceases early, owing—as we have learned from Zondek's investigations—to diminution in the formation of the gonadotropic hormone. Individual symptoms, such as falling out of hair and teeth, drowsiness, amenorrhoea, emaciation, apathy, pallor, have no special significance as they may also be due to disease of other glands. Lack of appetite, vomiting, adynamia and pain in the gastric region occur mainly in Addison's disease. It would be much more useful if exact hormone analyses could be prepared, and if it could be mathematically established how many units of each hormone were lacking. As things are, the individual imagination has a wide field. I am, however, decidedly against the administration of insulin, having observed only bad results therefrom, while I share Lucke's opinion as to the extreme sensitiveness to insulin of persons suffering from Simmonds' disease. The hypoglycaemia of the patient cannot tolerate any further reduction by means of insulin. In such cases it does no good, but only harm.

So far I have observed no case which resisted treatment by hypophysis pars ante. hormone, but I do not

Fig. 4. Case II—After treatment.

dispute the possibility of such resistance. We must not forget, however, that it has been possible to arouse from diabetic coma patients who had already been given up by giving them 1,000-1,500 units of insulin, instead of the otherwise usual 100-200 units. Perhaps the patients' resistance to this treatment was due to the fact that the preparations formerly used were not sufficiently concentrated. Naturally, even a hormone treatment cannot cure the patient if a tumor is pressing upon the anterior lobe, or if a metastasis occurs in the lobe.

Falta used to refer to primary anorexia, while Bergmann speaks of "absent appetite" (Aehlender Nahrungstrieb). What is the cause of this symptom? The same as that of low blood sugar, emaciation and low

Fig. 5. Case II—One year after treatment.

bodily temperature. The patient is not suffering from Simmonds' disease because he has no appetite; his lack of appetite is due to the tissues being unable to use the energy supplied. The lack of appetite is, as it were, a semaphore which is set at "Stop" for food. Bergmann frequently emphasizes the significance of *disorders in the gastric region*. The majority of the patients do in fact complain of such disorder. My first patient vomited continually, and was under the impression that the oculist who was treating her at the time had dropped something poisonous into her eyes. My last patient had also gastric trouble and complained of oppression and a feeling of fullness, vomiting and an unpleasant, but otherwise undefinable, weakness. Many doctors would be inclined to advise an operation in such cases, and it is probable that for this reason laparotomy is sometimes performed without any need, as Bergmann correctly states. To guard against such unpleasant mistakes there is only one remedy: a reliable and thorough X-ray examination. In cases where an elderly, carcinomatous-looking patient "forgets" to die, or where an apparently tuberculous patient is found to have normal lungs, Simmonds' disease should be suspected. An important symptom is the *decline in basal metabolism*, although it is at present difficult for the general practitioner to establish such diminution, while opinions as to the Read formula are still divided. Kestner considers the absence of the *specific dynamic action* to be a highly important symptom. I myself have no experience in this field.

Cases of serious gastric disorders in which the X-ray and chemical examinations have given negative results lead one to suspect some endocrine derangement. Such cases are most likely to come under the notice of clinicians who are at the same time radiologists. While the radiologist can gather nothing from negative results, the clinician will find therein a valuable guide. Bergmann attributes the gastric trouble to the hypophysis, which plays an important part in the digestive tract; he holds the view that the posterior lobe is also affected. In my opinion gastric disorders are not due to a diminished function of the posterior lobe of the hypophysis but to a decreased activity of the suprarenal bodies, and such disorders respond rapidly to cortical hormone, as also to hypophysis (anterior lobe) hormone. Kalk obtained good results by giving his patients grape sugar, without insulin. Although this may be useful as a therapeutic adjuvant, it certainly cannot replace the hormone treatment.

Experience teaches that the diagnosis of Simmonds' disease is very difficult. No diagnostic skill, no reading, however wide, can avert the danger of failing to recognize the disease. In two very serious cases there were, so to speak, no symptoms. This observation was also made by Reiche, for which reason he refers to rudimentary and atypic forms of disease. A serious illness may be developed without a single symptom affording guidance. Moreover, no symptom is a trustworthy guide, for each may be caused by a different gland. *The most reliable indication is the curative action of the specific hormone*; the "ex juvantibus," which is, in view of the excellent and concentrated preparation now obtainable, the most valuable and the most reliable guide. A precise diagnosis of the malady is in future to be expected only from a reliable hormone investigation. I am at present occupied with a diagnostic test in this connection, and hope to be able soon to begin the necessary work. My ideas run on the following lines:

A pregnant woman secretes quantities of gonadotropic hormone. In the pregnant woman there is a sufficiency of hormone, in a person suffering from Simmonds' disease there is a deficiency. If I now give a normal person an injection of hormone in the same quantity as that secreted on the average by a pregnant woman, the excess amount will be discharged from the body in the urine. If I give the same quantity to a person suffering from Simmonds' disease, it is not discharged because the hormone is fixed by the hormone-starved organism. Thus, while in a normal organism the Zondek reaction occurs after x hormone units have been injected, is this reaction absent in a sufferer from Simmonds' disease? The difference between the two quantities of hormone given to the two persons by injection shows the extent of the patient's hormone insufficiency.

A counter test to this would be as follows: The "Simmonds" patient is given an injection of hormone in such a quantity that his urine shows the Zondek

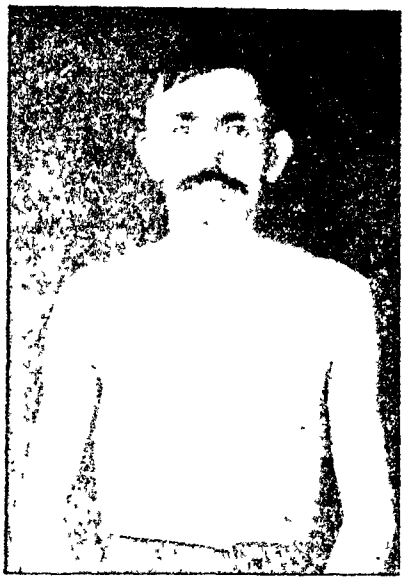

Fig. 6. Case III—Before treatment.

reaction. For this purpose a considerably larger quantity of hormone will be required than in the case of a normal person. From the amount of hormone administered the patient's hormone-producing capacity may be deduced; in healthy persons it will certainly be different from that of sufferers from Simmonds' disease. The purpose of this test would be to provide quantitative figures for the diagnosis of Simmonds' disease. This figure will be more or less constant in the case of healthy persons; in sick persons, however, it will vary. In cases where considerably more hormone units are required to induce the Zondek reaction, a hypofunction of the anterior lobe is present. This will enable a more exact diagnosis of Simmonds' disease to be made than heretofore.

Whether this conception will or will not prove useful in practice, only the future can show.

Another interesting question is: Why does coma never supervene in Simmonds' disease? It occurs in diabetes, in Addison's disease, and even in exophthalmic goitre. The cause may be found in the following facts: The disease itself is chronic, its course is slow and without any acute shocks. The organism does not lose strength suddenly, but only very gradually. Another cause may be that the ratio of the three main sources of energy—albumins, carbohydrates and fat—remains the same during the illness as in health. There is a general diminution, but not a disproportionate one. Here there is no deficiency of carbohydrate as in diabetes, nor any derangement of albumin metabolism as in exopthalmic goitre. Perhaps it is the existence of the normal ratio—even though on a greatly reduced scale—that safeguards the patient from the sudden occurrence of toxic symptoms.

Now the further question arises: which hormone is really contained in the well-known preparations Glanduantin, Prolan, Horpan, and Prehormon? As far as we know, it is the gonadotropic hormone. This is, however, contradicted by the action of these preparations whereby metabolism is markedly improved. What follows from all this? Either the much-discussed metabolic hormone does not exist or it is identical with the gonadoptropic hormone, or else both are contained in the preparations now on the market. In my patients, as regards the genital glands, I observed either no improvement at all or only a very slow one—in elderly persons this is, of course, readily understandable.

On the other hand, a marked improvement in the patients' metabolism invariably occurred. The fact is, therefore, clinically important: that I have always observed a remarkable improvement in metabolism as the result of gonadotropic hormone.

It is also gratifying to note that the *therapy of the disease* has progressed. In his earlier articles, Reye already emphasized the good results obtained by administering hypophysis fresh from the slaughterhouse. Since then research work has made great progress, while science has enriched us with excellent remedies, which are deserving of the highest praise. *Most of my experience has been with Richter's Glanduantin*, which I consider to be a means of saving life in cases of Simmonds' disease. Its action is equally reliable here as that of insulin in diabetes, with this great difference: that in 2-3 months the patients have so far regained their strength that no more hormone is needed. Glanduantin is not a substitution remedy but a real cure. I have had similar results with Prolan and Preloban; also of Pregnyl, a Dutch preparation, Horpan, a Dresden preparation, and Prehormon, a product of the Promonta Factory, I have nothing but good to report. With these preparations the physician can obtain amazing results. I am already inclined to believe that in view of these excellent and highly concentrated preparations (ampoules with 500 units are already obtainable), the dosage of which can be accurately determined, no single sufferer from Simmonds' disease need die of it, provided the doctor is able to recognize the malady. When we consider what successful work has been achieved by Simmonds, the gifted pathological anatomist, of Hamburg, Reye, the distinguished Hamburg clinician, and Bernard Zondek, the world-famous hormone student and gynaecologist, it is difficult to refrain from declaring

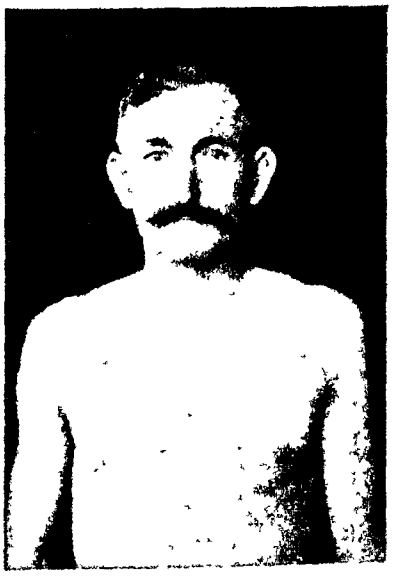

Fig. 7. Case III—After treatment.

emphatically that these men are among the greatest benefactors of mankind.

As regards the dosage, no fixed rules can be laid down. It is impossible to say whether 100 or 200-300 units a day will be required. It depends entirely on the individual. I had patients who felt well when taking 100 units a day and others when taking 700 (seven hundred) units a day. The proper daily dose for the patient is that quantity of hormone on which he gains weight. It varies greatly. Sometimes the increase in body weight begins late, but an improvement soon appears in the gastric symptoms, while the appetite and muscular strength increase; this improvement is accompanied by a subjective but, for the doctor, highly significant symptom: an amelioration of the patient's peculiarly unpleasant general feeling. "I don't feel so queer now" is a stereotyped saying of such patients. When these signs appear, the dosage is suitable. Whenever we are able to determine quantitatively from the urine the insufficiency or any improvement in the separation of the hormone, then we shall also be able to prescribe the dosage with mathematical precision. For the time being, it is important to note that even the present therapy is successful and represents one of the greatest achievements of medical research.

I will not venture to say that the correction of the pathological process is effected by the hypophysis hormone alone. Moreover, we do not know how and in what manner it acts. It is possible that the mere presence of the hormone is sufficient; perhaps it regulates the activity of the neighbouring large vegetative centres. In his excellent book, Raynaud speaks of "signes d'emprunt," i.e. of symptoms which are "borrowed" from the neighbouring vegetative centres, but it may be possible that the vitamins also play some part in the process—a theory which I consider highly probable. References to a connection between the vitamines A, C, D and E and the hypophysis are appearing with increasing frequency in medical literature (Verzár, Vogt, Moravitz, Abderhalden, Kühnau). Possibly, the hormone stimulates some process which paves the way for the necessary vitamin or perhaps neutralizes the effect of an opposite vitamin. In the cogwheel-like arrangement of the endocrine system it may easily be that the failure of one factor impedes the other factors. However that may be, one thing is certain: that the anterior lobe hormone plays a dominant part in the treatment of Simmonds' disease, irrespective of whether the action takes place directly or indirectly. Further research will throw light on the intricacies of the working mechanism.

Value of a Routine Red Cell Sedimentation Test in Gastro-enterology*

By

MEYER GOLOB, M.D.

and

HARRY BOROWSKY, M.D.

NEW YORK, NEW YORK

PATIENTS attending a clinic for gastro-intestinal disorders usually complain of symptoms referable to the digestive system. Investigation however, often shows that the cause of the symptoms lies, not only outside the gastro-intestinal tract, but frequently outside the abdomen altogether. Aware of this, the gastro-enterologist must not let himself be misled by the patient's concentration upon digestive manifestations. He must rather, look beyond his own specialty, considering the patient as a human being—not as a mere digesting mechanism.

Therefore, the red cell sedimentation test as applied in the broader field of general medicine, including ailments remote from the digestive tract, may very well become a valuable aid in gastro-enterological diagnosis. Even though a negative finding with the red cell sedimentation test does not positively exclude the existence of disease, the value of a *positive* sedimentation is in no wise lessened. When this is the only evidence of disease it may well excite the examiner to greater care, and has in many instances thus enabled wholly unsuspected pathological states to be made manifest. Thus its employment in a gastro-intestinal clinic, where cases of both types are continually encountered, will be as beneficial and helpful as this test has long since proved itself in clinics devoted to gynecology or the control of tuberculosis.

Many authors have shown how closely related are the affections of the female genital tract and the gastro-intestinal system, while the relations which any type of tuberculous infection will establish with both these systems is too well understood to need more than passing mention. Runyeon (1) has illustrated this in the instance of the Krukenberg tumor, while Friedenwald and Morrison (2) have made an elaborate analysis of the reciprocal relationship between gastro-intestinal disturbances and pathologic conditions in the female pelvic cavity. It has been clearly demonstrated that such a test has practical clinical application in many conditions wherein it has not up to the present time, been used.

THE TEST

What we have here termed the *red cell sedimentation test* is known by a number of different designations. Since its introduction by Fahreus (3) in 1918 it has been called simply "the sedimentation reaction," or been known as

*From the Gastro-intestinal Department of the New York Homeopathic Medical College and Flower Hospital.
Submitted December 3, 1935.

'the suspension stability reaction of the erythrocyte,' 'rapid cell sinking' or 'rapid cell settling,' or again as the 'acceleration of sedimentation velocity.' All these refer to precisely the same phenomenon, which may be briefly described as follows:

Sinking of the red blood corpuscles takes place in the *presence of an anticoagulant, leaving a clear plasma.* This sinking is more rapid when disease is present, than when the body is healthy. This test appears to be the acme of simplicity, but it must be emphasized that its proper interpretation is not the function of the laboratory technician, but must be made by the clinician himself, as he alone is able to translate the findings in terms of all the other factors essential to recognition of disease in the body of the patient whose blood gave positive findings to the test.

The cell *sedimentation rate* is distinctly separate from the sedimentation *time*. For the time is inversely proportional to the severity of the disease; i.e. when the rate is increased, the time is lessened. The phenomena most significant for the test occur during the first hour. Beyond that period very little information of value can be obtained. Of the many hypotheses advanced to account for these phenomena, that most generally accepted is that in the presence of disease there is increased tissue destruction and the liberation of fibrinogen in the blood stream, with ensuing clumping of the cells. The larger the clumps, the more quickly will they sink.

INTERPRETATION OF THE TEST

Charting the sedimentation values in different types of cases, Cutler (4) obtained four graphs which he names horizontal line, diagonal line, diagonal curve, and vertical line. "Of these," he writes, "the horizontal line alone is normal. The other three graphs are always abnormal findings and always indicate different degrees of the intensity of the destructive process." "Its chief value," remarks Haskins (5), "is not in differential diagnosis but in following the course of the individual case, and in giving a clue to unsuspected infection, inflammation or malignancy in persons in whom a normal rate has been expected." In much the same strain Bannick (6) calls attention to three general principles: (1) An increased sedimentation rate always indicates the presence of disease of some kind; (2) but a normal rate does not exclude the presence of disease. (3) The rapidity of sedimentation is a measure of the severity of the disease, and when a level has been established in a given case, the rapidity of sedimentation provides a measure of the progress of the disease in that case.

That apprehension on the part of the patient may be a factor in erroneous readings of the test, is pointed out by Van Antwerp (7). To obviate this chance of error, he performs two sedimentation tests on successive days upon all newly-admitted patients. The lower of the two readings is accepted as reflecting the presence or absence of a destructive lesion.

VALUE OF THE TEST IN PEPTIC ULCER AND CANCER

A reliable means of differentiating between malignant and benign lesions of the digestive tract has long been sought by gastro-enterologists without avail. Does the red cell sedimentation test fill this need? Rubin (8) avers that in its early stages cancer does not necessarily induce an increased sedimentation rate, and cites a case of carcinoma of the esophagus, wherein the patient, otherwise in good physical condition, had a normal rate. Eleven months after the test was made the patient was returned to the hospital, and died shortly after of cancer, thus demonstrating that the sedimentation test may be unreliable when malignancy is in a very early stage.

As regards peptic ulcer, or its differentation from gastric cancer, Rubin, writing in collaboration with Morriss (9), and later (10), makes several citations from literature tending to indicate that the sedimentation test is of diagnostic aid when ulcer must be differentiated from cancer of the stomach, as cell settling has been shown to occur more rapidly if the lesion is malignant. Our own findings, in a comparatively small series of cases, tends to confirm the views which Rubin quotes. We agree with Held and Goldbloom (11) who found that though the sedimentation

Abstract of one hundred gastro-enterological cases and control study of twenty-two normal senior medical students

Disease	No. Cases M	No. Cases F	Low — High M	Low — High F	Average M	Average F	Remarks
Neurosis	17	9	2-13	4-13	5.05	8.07	In these cases, normal sedimentation rates, with negative physical findings led to the diagnosis of functional disturbance.
Chronic gall bladder disease	2	9	25-26	14-24	25.5	19.8	Clinically, the rate parallels the activity of the disease.
Calcified gall bladder		1		4		4	In this single case the low rate showed the disease process to be inactive, indicating an environment unfitted for microbic activity.
Duodenal ulcer I. Without bleeding or obstruction	6	2	2-14	14-14	6.8	14	The test here gauges the activity of the lesion, with bleeding as the main feature. In one case, the active ulcer showed 37 mm., but only 7 mm. in the latent period. Hemoglobin index rose as sedimentation rate fell. Lesions of the posterior duodenal wall bled more, and therefore show a more rapid sedimentation rate than those on the anterior wall.
II Bleeding, with and without obstruction	7	2	15-37	16.5—19.5	23.2	18	
Carcinoma of gastro-intestinal tract	4	3	15-37	26-28	24.8	26.3	In differentiating between benign and malignant gastric ulcer, if a high sedimentation rate is obtained in the presence of bleeding, it is not so indicative of malignancy as a high rate when bleeding is not conspicuous. Rapid sedimentation may occur independently—before characteristic symptoms appear. Rapidity of rate apparently parallels advance of the disease process.
Benign achylia gastrica	2	6	3-4	2.5—7.5	3.5	5	In true achylia gastrica the sedimentation test differentiates between benign and malignant types, a high rate usually indicating malignancy.

Miscellaneous Cases. Too Few to Permit Conclusions to be Drawn From Them. (Rapid red cell sedimentation fixes attention, leading to further observation and repeated testing to reveal the lesion; normal rate of sedimentation, correlated with other negative factors, justifies the assumption that disease is not present)

Disease	Number of Cases	Rate in MM.	Remarks
Acute retrocecal appendicitis	1	25	This case presented the classic symptoms of cholelithiasis; the white count showed a polymorphonuclear leukocytosis, with a marked shift to the left. Gall bladder normal cholocystographicly.
Acute suppurative appendicitis	1	30	Clinically unusually quiescent, operation in this case revealed appendiceal suppuration.
Vague gastric disturbances; metrorrhagia	1	23	Nullipara, 40, no miscarriages; husband's blood Wassermann repeatedly negative; own Wassermann, 4-plus. Vague symptoms of indigestion; diplopia following influenza; no clinical lesion demonstrable. Patients with positive Wassermanns but showing a normal sedimentation, appear to have latent syphilis. The test, therefore, differentiates between latent and clinically active syphilis.
Dental sepsis; gastric disturbance	1	7	
Irritable colon	2	11	
Lamblia duodenitis	1	23	
Glenard's disease	3	6-15	
Gastric hyperacidity	5	4-16	
Deferred diagnosis	7	3-25	
Gastric hyperacidity	6	4-16	
Umbilical hernia; hyperchlorhydria	1	8.5	
Tuberculous pleurisy	1	23	
Neurosyphilis	1	12	
Syphilis	1	Norm.-7	
Amebic ulcerative colitis	1	30	
Non-specific ulcerative colitis	1	23	
Periodic health examination	1	15	
Neurogenic diarrhea	1	4	
Diverticulosis; diverticulitis	1	27	
Gastro-enterogenous diarrhea; cholecystectomy; infection	1	17	
Acne and vague gastric disturbances	2	13-16	
Graves' disease	1	7	
Nutritional anemia	1	15	
Erythremia (persistent polycythemia or Vaquez's disease)	1	0	
Migraine of biliary (?) origin	1	21	
Cardiospasm	1	15	
Non-infectious granuloma abdominis	2	2-14	
Diabetes mellitis	1	19	
Major epilepsy	1	4	
Ulcer at pyloric end of stomach	1	12	
Pregnancy	1	19	
Roentgenologically diagnosed appendicitis	1	3	
Pyorrhea alveolaris; reversed peristalsis (Alvarez syndrome)	1	7	
Anxiety neurosis; (fear of appendicitis)	1	11	

Control Tests On Healthy Individuals

The normal controls were recruited from the senior class (1935) of the Homeopathic Medical College and Flower Hospital consisting of 22 male students. Only apparently healthy individuals, free from cold or any infectious conditions were asked to submit themselves to the test.

The following results were obtained:

Highest sedimentation rate	11 mm.
Lowest sedimentation rate	1 mm.
Average	4.3 mm.

All these readings are well within normal limits, and go to show, despite the very small numbers tested, that in individuals proved healthy after adequate physical examination, the sedimentation phenomenon will present a picture in no wise varying beyond normal limits.

rate was not increased in benign ulcer, when carcinomatous degeneration took place in such an ulcer, the rate was increased very regularly. All of our own cancer cases have shown a rapid erythrocyte sinking. We are therefore, of the opinion, that the red cell sedimentation test has distinct diagnostic value when striving to differentiate between ulcer and cancer of the gastro-intestinal tract. The findings of such authors as Barthold (12), who claims that the test is valueless in either extreme of the malady—the very early case or that which has advanced to the stage of cachexia—do not, in our opinion, find any application in the general run of cases seen in routine gastro-enterological practice. The results of investigations made by Lorie (13) several years ago, bear out our views. We would suggest that a gastric ulcer, in the presence of a low rate of settling, may be regarded as benign, if there is no associated gastris or duodenitis.

Relation of the Test to Hemoglobin Readings: The relation of hemoglobin to the red cell sedimentation findings was studied by Rubin and Smith (14) almost a decade ago. Most of their findings have been paralleled by our own experience. We found, for example, that a high hemoglobin count accompanied augmented sedimentation. Any diagnostician will agree that a high hemoglobin count, considered by itself merely serves to increase confusion, but if we can interpret it in terms of rapid cell sinking, it becomes at once a valuable diagnostic factor. The statement that "the hemoglobin content of the red blood cells parallels to a certain degree, the erythrocyte sedimentation reaction," was substantiated by our own experience. We have not kept a complete account of the relationship of the red cell count to the sedimentation results, but the few records regularly reveal a very close alliance—a low hemoglobin index implied augmentation in red cell sinking.

Achylia Gastrica: Though the differentiation between benign and malignant achylia is quite well standardized, the red cell sedimentation test should be of service in the diagnosis of this condition. The sedimentation rate has been shown to be unaltered in benign achylia, but increased in the malignant forms. True achlorhydria may be benign in a benign gastric tumor, when the sedimentation rate will be normal. But should the nature of the growth change, as in that mentioned by Sanders (15), demonstrated by Rubin at Montifiore Hospital, when the tumor develops central necrosis, or becomes infected, a rapid sinking of the red blood cells will be immediately perceptible. And the rapidity of this sinking will furnish an index of the extent and severity of malignant tissue destruction. The achylia of syphilis or pernicious anemia, or that frequently associated with a tuberculous infection, if estimated by the red cell sedimentation test, must be interpreted in terms of these respective maladies.

Bleeding and Non-Bleeding Peptic Ulcer: The anemia resulting from a bleeding gastro-duodenal ulcer alters the normal sedimentation rate. When bleeding ceases, the rate of red cell settling approaches normal, and thus points to a propitious time for surgery, if the case be one where surgery is otherwise indicated. This analogy holds good for mucus colitis, as well as cholelithiasis, both uncomplicated, or with attending inflammation.

The cases included in the first part of our Table presented generally similar characteristics: Hyperchlorhydria, a hemoglobin index ranging from 36 to 54 per cent, a red cell count of from 2.5 million to 3 million, and a sedimentation rate between 22 mm. and 38 mm. in 60 minutes. The duodenal cases showed the classic syndrome of a post-pyloric lesion, marked hyperchlorhydria with persistent deformity of the bulb, though the lesion did not cause obstruction and did not bleed; a hemoglobin index of 95 per cent, and a red cell count of five million. The sedimentation rate was regularly a horizontal line—2.2 mm. in 60 minutes. The value of the red cell sedimentation test in such instances is certainly obvious.

In the tedious period of convalescence which marks these ulcer cases, the test serves as a continual guide and check upon treatment. Should erosion of a blood vessel bring about sudden hemorrhage, the extent and activity of the bleeding, with the degree of tissue destruction involved will be registered in the behavior of the erythrocytes every time the test is applied. After surgical intervention, an increased sedimentation rate indicates the amount of traumatic tissue damage and the different phases of the absorption process. A persistently high sedimentation rate gives strong evidence of the existence of a complication. Yet the test must not be regarded as a substitute for blood cytology. Indeed, it is not a *substitute* for anything. It is an *addition* to all the previously employed methods. It even has psychic aspects. Gallagher (16) has employed it to detect evidences of chronic disease in subjects whose past history suggests the possibility of its existence. He avers that "The finding of a normal sedimentation rate has given us greater confidence in the advisability of expectant treatment, and in our attempts to reassure the patient."

Anemia Due to Colon Malignancy: Differentiating the various degrees of anemia due to bleeding of malignant lesions in the colon, necessitates taking into consideration the precise location of such lesions. As Heald (17) has put it, "The blood picture differs with the location of the lesion. It is a well established fact that secondary anemia is more marked with right side tumors than with left." The right half of the colon is of greater calibre, permitting larger growths to develop with more bleeding surface, and a resultant higher grade anemia. In the right half moreover, adenocarcinoma is the prevailing type of neoplasm, in contrast to the annular, constricting type likely to be found in the left half of the colon. Since the rate of red cell sedimentation varies with the degree of anemia, a higher rate would, therefore, point to a malignant lesion in the *right* colon. A large bleeding surface in the right colon may induce a blood picture readily mistaken for that of pernicious anemia. In this type of case every "lead" is of value, and the application of the sedimentation test may give invaluable evidence as to the location and extent of the lesion, and the severity of the tissue destruction—perhaps even resulting in a saving of priceless time sufficient to evert a fatal termination of the disease.

To the gastro-enterologist, as to medical practitioners in all divisions of the science, the red cell sedimentation test should prove an invaluable aid. While alone and unsubstantiated, it will not serve for differential diagnosis, or even demonstrate the presence of any given disease, nevertheless it serves to warn the clinician that disease of some kind is present. As the speed with which the red corpuscles sink is in direct proportion to the intensity of this disease process—though we must allow for the factor of anemia—a *postive* finding is a most valuable aid in diagnosis, even if a negative result does not necessarily indicate that *no* disease is present.

CONCLUSIONS

1. The red cell sedimentation test merits a place in the diagnostic equipment of the gastro-enterologist, as an aid in the diagnosis of diseases in which infection or tissue destruction are important factors.

2. Where no direct external evidence of disease exists, but the test shows a departure from normal conditions, the examiner will be stimulated to further scrutiny of the available evidence. This is of particular importance where a neurasthenic state, or frank neurosis is present, as under these conditions a normal sedimentation rate will assure the examiner

that he is not overlooking a physical ailment which is masked by the psychic state.

3. The test does not supplant any diagnostic measure now employed, but provides additional confirmation of their findings.

4. Though the present study is admittedly limited in respect to the number of cases, it offers convincing evidence as to the value of the test in determining the activity or latency of a malady, giving information as to tissue breakdown such as occurs in malignancy, or if inefficiency of the blood-forming mechanism, as in anemia due to excessive hemorrhage.

5. Since many wholly unrelated pathologic conditions produce symptoms apparently referable to the gastro-intestinal tract, the routine application of this test should operate to separate those cases within the gastro-enterologist's province from those which properly belong to other specialists. To illustrate: If the gastro-intestinal examination showed no lesion in the canal, a normal stomach chemistry, and an X-ray film without filling defects or other evidence of pathologic distortion, then an accelerated sedimentation rate should at once stimulate a search for a disease condition unrelated to the digestive canal.

6. The red cell sedimentation test resembles the leucocyte count in that it is not specific for any disease even when positive, and if negative does not necessarily indicate that *no* disease condition is present.

7. In the presence of a known pathological condition normal sedimentation indicates that the disease process is inactive; a speedy sinking of the red corpuscles indicates that the converse is true. The test can, therefore, be utilized as an aid in prognosis.

8. The present study is based on 100 consecutive clinic cases wherein the sedimentation test was employed, and upon the results obtained by applying the test to 22 normal individuals who volunteered to act as controls.

The writers wish to express their appreciation of the help and interest of Dr. Addie Stanford in the work here recorded, as well as to the members of the graduating class of 1935, without whose assistance it could not have been brought to an adequate conclusion.

Bacteriological Findings in Disease of the Biliary Tract*

The Relationship of Gastric Acidity to Biliary Tract Infection

By

JOHN RUSSELL TWISS, M.D.

and

EILIF C. HANSSEN, M.D.

NEW YORK, NEW YORK

THE determination of infection of the biliary tract has presented such a variety of technical difficulties that there are no published reports in which the diagnostic value of biliary tract drainage has been entirely confirmed. A further complication of this situation is that there is little information available as to biliary tract infection and its relationship to gastric acidity. Whipple (1) in a series of 25 patients going to operation reported that organisms similar to those found in cultures of the biliary tract were obtained in the pre-operative duodenal drainage bile in 54%. This percentage of accuracy in diagnoses suggests that the duodenal drainage findings represent a casual rather than a diagnostic relationship to the actual conditions of infection in the biliary tract. Lyon (2) in another series reported a majority of cases showed similar findings, no definite figure being available. Among others Boardman (3) and Nauss, Lake and Torrey (4) have questioned the value of

sterile cultures of duodenal bile on the basis of comparison with clinical findings and known results of cultures obtained at operation.

Hanssen and Yurevich (5) have shown the great discrepancy between the numerous varieties of bacteria reported in cultures of duodenal bile and the few actually found in the biliary tract at operation. These authors found that, in a study of 104 patients coming to operation, the biliary tract was sterile in 67 per cent. Where infection occurred a single variety of organism was found in 95% of the cases. Biliary tract drainage of these patients, on the other hand, showed sterile cultures in only 25% of the drainages and a high proportion of mixed cultures. Agreement between drainage and operative findings occurred in 54% of the cases. While it is obvious that although the drainage findings showed the same apparent confirmation as in other series, here the bacteriological findings were actually of little diagnostic value.

In view of the unsatisfactory status of duodenal drainage as a means of determining biliary tract infection, an improved method of taking sterile cultures of duodenal bile, using an encapsulated tube, was recently devised and described by Twiss and Phillips (6). The purpose of this method is to eliminate contaminations of the bile externally, and internally by sealing off the duodenal tube while it passes through the mouth and stomach. In a series of patients studied by both this method and by a modification of the one of Lyon (7), (elsewhere described) (8), the encapsulated method showed in the duodenal bile only a third as many varieties of organisms similar to those of the mouth, three times the number of sterile cultures and half the number of mixed cultures. The fact that even findings with this method have not been entirely in accord with operative findings has led to further investigation.

The pathway of the pathogenic bacteria into the alimentary canal has been well described. Data on the bacteriology of the mouth, showing the prevalence of organisms in the crypts and salivary secretions, has been summarized by Arnold and Stuart (9). These authors have noted the impossibility of sterilization of the mouth, as has Boardman (3). The many bacteria gaining access to the stomach with saliva and ingested food have been described by Cotton (10) and Kopeloff (11). The usual presence of bacteria in the stomach with achylia was shown by Rehfuss (12).

TABLE I

Varieties of bacteria found in duodenal drainages of 355 patients. Patients are classified according to findings of free hydrochloric acid in the fasting gastric contents

Group	Achlorhydria Patients		Normal Acidity Patients		Hyperacidity Patients		Total	%

Total	55	63	52	30	23	24	130	

Group I Achlorhydria — Free hydrochloric acid 0
Group II Normal Acidity — Free hydrochloric acid 0 to 20
Group III Hyperacidity — Free hydrochloric acid over 20

The normal variations in the amount of free hydrochloric acid in the gastric contents have been described by Vanzant, Berkson and Alvarez (13), whose "normograms," based upon the study of 3,746 normal subjects, show that in the age group from 20 to 75, the mean hydrochloric acid of the stomach is in males, 33-47, in females, 31-33. A further study has been made of gastric acidity associated with disease of the gall bladder by Vanzant, Alvarez, Berkson and Eusterman (14). These authors studied 602 patients operated upon, with and without stones, and concluded that although there was a slight increase in the incidence of patients with achlorhydria, in general there was little deviation from the normal in either men or women.

The normal duodenum in the fasting state has been shown to be sterile by Cushing and Livingood (15), Mac Neal and Chace (16), Kellogg (17) and others. The protective bactericidal power of the gastric secretion in maintaining the sterility of the upper intes-

tinal tract, ascribed mainly to the presence of free hydrochloric acid, has been noted by Hurst (18), and suggested by the duodenal drainage findings of Bartle and Harkins (19), who found in a study of 200 patients that the duodenal bile was sterile in 35% of the hyperacidity patients and 20% of those having an achlorhydria. A summary of the findings of a higher incidence of bacteria in the duodenal bile in patients having an achlorhydria has been given by Nauss, Lake and Torrey (4). Hurst (18) reported in a series of patients with gall stones that 49% had achlorhydria and 23% hyperchlorhydria.

The only investigation which the authors have found in which the bacteriological findings at operation have been correlated with the gastric acidity of each patient is that of Moynihan (20), who found in a series of 81 patients hyperchlorhydria in 20% and achlorhydria in 22%. In the achlorhydria cases the gall bladder bile showed infection in 66%, in those patients having a normal or increased hydrochloric acid the incidence of infection was 28%. Moynihan interprets these results as indicating that infection through the duodenum does occur and that this is more likely to occur with achlorhydria. This author agrees with Knott (21) that the probable mechanism is that the lack of free hydrochloric acid results in a loss of the "germicidal barrier."

A relationship between bacteriological cultures of bile obtained by means of the duodenal tube and the acidity of the gastric contents was also suggested by our own studies, in which wide variations in the bacteriological findings of the duodenal drainage bile were noticed in studying different groups of patients. These differences were found to coincide with the variations in gastric acidity, those patients having gastric hyperacidity were found seldom to show viable bacteria, while the majority of the positive cultures of duodenal bile seemed to occur in those having a diminished or absent free hydrochloric acid.

AUTHORS' STUDY

During the past five years 2000 patients suspected of having disease of the gall bladder have been studied in the combined Medical and Surgical Clinic for Diseases of the Liver and Biliary Tract of the New York Post-Graduate Hospital. The purpose of the present article is to present the bacteriological findings of the duodenal bile in a series of 355 patients, classified according to gastric acidity, upon whom cultures of the duodenal bile were made in 550 drainages under sterile precautions. A further series of 120 patients was

studied, in whom cultures of the gall bladder bile, the gall bladder wall, the cystic duct node, and stones if present were made at the time of operation. The results of cultures from operative specimens and from the duodenal bile in relation to the gastric acidity are given for 86. Bacteriological cultures of the duodenal bile and operative specimens were made under the direction of Dr. Adele Sheplar, according to the methods described by Hanssen and Yurevich (5).

In this study, we have arranged our patients into three groups on the basis of the amount of free hydrochloric acid found in the fasting gastric contents at the time biliary drainage was performed. In practically all cases, the drainages were done repeatedly. We have placed in Group I all patients showing no free hydrochloric acid in the fasting gastric contents, indicating a deficiency in free hydrochloric acid. Group II includes those having an average amount of free hydrochloric acid, with readings from 0 to 20. (The number of c.c. of N 10 NaOH required to neutralize 100 c.c. of gastric contents). This group corresponds to the normal acidity group of Alvarez and his associates. The fasting gastric contents are considered to have approximately half the amount of free hydrochloric acid shown in the fractional test meal. All patients having free hydrochloric acid over 20, which we consider a relative hyperacidity, are placed in Group III.

The bacteriological findings in the duodenal bile cultures of 355 patients not coming to operation are shown in Table I. The hyperacidity group here shows an incidence of sterile cultures nearly double that of the achlorhydria and normal acidity groups. The incidence of mixed cultures in the achlorhydria group is 6 times that of the hyperacidity group. In those patients showing only one or two varieties of bacteria, the achlorhydria group showed an incidence of infection more than double that of either of the acidity groups. The staphylococci and streptococci predominate in all groups, particularly with achlorhydria, where mouth contaminants are also more prevalent

TABLE IV

Frequency of occurrence of organisms in the biliary tract at operation, in patients classified according to gastric acidity

B. coli, however, shows a definitely increased incidence in the achlorhydria and normal acidity groups.

A comparison of these findings with the operative bacteriological findings in a series of our patients, as shown by Hanssen and Yurevich (5), indicates again a wide discrepancy between the incidence of infection in the duodenal bile cultures and those cultures taken at the time of operation.

The results of duodenal cultures taken by means of the encapsulated tube are therefore shown with those of the unencapsulated method in Table II. Here we see that the encapsulated method shows cultures more in accord with the operative findings, the percentage of sterile cultures being higher in all groups and reaching 66% in the hyperacidity group. As before stated, 67% of the patients showed sterile cultures of all parts of the biliary tract at operation. It is further worthy of note that although the bacteria in general were the same as found by the other method, practically no mixed growths of bacteria, indicating contamination, were obtained by the encapsulated method in patients having free hydrochloric acid in the gastric contents. Of 5 patients in whom the biliary tract was sterile at operation, having pre-operative duodenal drainage by the encapsulated method, 4 showed sterile cultures in all specimens.

To determine the actual incidence of biliary tract infection and its relationship to gastric acidity a study was made of 120 patients operated upon, the findings are shown in Table III. The series as a whole showed a distribution of 40% of the cases in both Groups I and II, 20% in Group III. Of the entire group 60% of the patients showed calculi. The incidence of infection in the calculous and non-calculous groups was approximately the same as in the whole group, indicating no definite relationship between infection and the presence of gall stones. On the other hand a definite relationship is suggested between gastric acidity and the presence of infection, as well as stones. In the achlorhydria group the incidence of infection is approximately twice that of the normal acidity group, the achlorhydria group also showing a somewhat higher proportion of calculous cases.

The varieties of bacteria found in the biliary tract at operation are shown in Table IV. In the achlorhydria group the incidence of infection is seen to be nearly twice that of the hyperacidity group and nearly three times that of the normal acidity group. Bacteria were found more frequently in the gall bladder bile of those patients having stones who were deficient in free hydrochloric acid than in those having no stones. The bacteria found may be grouped into those occurring predominantly in the achlorhydria group, which include the colon infections, the streptococci, and staphylococci. The only organisms occurring both with and without gastric acid are those of the typhoid and colon groups and the streptococcus non-hemolyticus. The third group, found only in those patients having free hydrochloric acid in the gastric contents, include the B. Welchii and the B. proteus.

It is here interesting to note that the organisms found in those patients having free hydrochloric acid are those which would apparently be little affected by gastric acid. The B. Welchii and B. proteus are known to be found normally in the liver, while the colon infections are considered to be brought to the liver through the portal system. Typhoid infections are usually considered to be of hematogenous origin. Knott (21) has also shown that typhoid and colon organisms are more resistant to the bactericidal action of acid in bile. The streptococci and staphylococci, however, seem in most cases to have been prevented from gaining access to the alimentary tract by the free hydrochloric acid in the stomach.

The results of duodenal drainage in the operative patients are shown in Table V. The bacteria here listed were found in the duodenal bile either in pure cultures or with not more than one other variety of organism. A comparison of the duodenal drainage cultures with the operative findings shows that in the achlorhydria group not all the varieties of staphylococci, streptococci and colon organisms occurred in pure growth in the duodenal bile, but were present as mixed growths of bacteria. In the normal acidity group the duodenal drainage findings were in most cases in accord with the operative, except that the staphylococcus albus was found in the duodenal drainage bile 5 times when not present in the biliary tract at operation. In the hyperacidity group the B. coli was not grown in the duodenal bile due probably to the inhibitory action of the free hydrochloric acid.

TABLE VI

A diagnostic comparison of pre-operative duodenal drainage cultures with the operative findings in 16 patients showing infection of the biliary tract at operation

Group	Achlorhydria	Normal Acidity	Hyperacidity	Total
No. of patients	10	3	3	16
Cultures identical with operation				
B. typhosus	2	1	2	
B. coli	3	0	0	
Streptococci	1	0	0	
Sterile	0	0	0	

Of the 41 patients found to have a sterile biliary tract at operation, duodenal drainage cultures were sterile in 14% of the patients in Group I, 38% of those in Group II, 72% of those in Group III. It is here apparent that the duodenal cultures were contaminated 5 times as frequently in the achlorhydria group as in the hyperacidity group. All patients having sterile cultures of duodenal bile were sterile at operation. In the 16 patients showing infection at operation, (Table VI) significant duodenal cultures were found in 9 or 56%. The majority of those patients showing a mixed growth or different type of organism, were in the achlorhydria group. The only organism present in the biliary tract at operation, found in pure culture in the duodenal bile, were those of the B. coli groups, the B. typhosus, and the streptococci. None of the patients showing infection of the biliary tract were drained by the encapsulated method.

SUMMARY

1. A survey is presented of the bacteriological findings of 355 patients upon whom sterile drainages were done and 120 patients operated upon for disease of the biliary tract, where cultures were made at the time

of operation of the gall bladder bile, the gall bladder wall, the cystic duct node, and stones if present. These patients are classified in relation to the gastric acidity of each.

2. In the 355 patients not coming to operation the incidence of sterile cultures of the duodenal bile in those having a hyperacidity was double that of the patients with an achlorhydria or a normal acidity, mixed cultures occurred 6 times as frequently in those with achlorhydria.

3. In the duodenal drainages performed upon the same patients by the encapsulated method, a higher percentage of sterile cultures were obtained in all groups. Practically no mixed cultures were obtained by this method in those patients having free hydrochloric acid in the gastric contents.

4. In 120 patients having had cultures of the biliary tract at operation, the incidence of infection in those with an achlorhydria was found to be about twice that of the group with a normal acidity. In this series the incidence of infection was the same in the calculous and non-calculous groups.

5. According to the number of varieties of bacteria found in the biliary tract at operation, the group of patients with an achlorhydria showed twice the number found in the group having hyperacidity and three times the number in the group having a normal acidity.

6. A study of the diagnostic value of duodenal drainage showed that in this series (1) in every case where the duodenal drainage cultures were sterile, the biliary tract was sterile at operation. (2) In no case where infection was present in the biliary tract were the duodenal bile cultures sterile. (3) In patients in whom the biliary tract was sterile at operation but who showed organisms in the duodenal drainage bile, most of the contaminations occurred in the achlorhydria group. (4) In patients with an infection of the biliary tract, the only organisms found preoperatively in pure cultures were those of the B. coli, B. typhosus, and streptococcus groups. (5) The staphylococcus albus, although found quite frequently in the duodenal drainage bile, was not found in the biliary tract of the same patients.

CONCLUSIONS

1. There is a definite relationship between gastric acidity and biliary infection, proved by pre-operative determination of gastric acidity and bacteriological studies of the biliary tract at operation.

2. Cultures of duodenal bile obtained by the encapsulated method show results more in accordance with operative findings in the same patients.

3. Interpretation of the results of sterile cultures of duodenal bile should be made only with a knowledge of the gastric acidity in each case.

The authors wish to express their indebtedness to Doctors Charles Gordon Heyd, Edward F. Peterson and R. Franklin Carter, for their permission to use the data concerning operative patients and cultured specimens, to Dr. Adele Sheplar for her collaboration in regard to the bacteriological work, and to Dr. Carl H. Greene for assistance in the presentation of this material.

SECTION II—*Experimental Physiology*

The Fate of Bacteria Injected Directly into the Cecal End of the Colon*

By

LOUIS WEINSTEIN, M.D.
NEW HAVEN, CONNECTICUT

MANY investigators have studied the fate of various bacteria, pathogenic and non-pathogenic, in the gastro-intestinal tract of man and animals. The usual method of carrying out this type of experiment has been to feed the organisms under investigation by mouth and then to attempt to isolate them from the feces of the experimental animals. This procedure involves great difficulty in the interpretation of results obtained: if the organisms do not appear in the stool, it is impossible to determine in what part of the gastro-intestinal tract they were destroyed. From the standpoint of the clinical investigator, this type of experiment is important, since in the usual types of enteric infections the causative organisms are ingested. However, to the experimenter interested in the physiology and bacteriology of the gastro-intestinal tract, it is of great importance to know in what portion of the intestine the lethal action, if there is such, is resident.

Various investigators have devised operations upon animals which allow the experimenter to introduce and remove substances from different levels of the intestinal tract. One of the most common operations of this type is the one by which a fistula is made in the cecum. Various objections to this type of operation have been made on the grounds of leakage and improper functioning. An improved method of making a cecal fistula has been devised by Cowgill and Weinstein (to be published) which eliminates the objections commonly made against the cecal fistula. Having on hand what we believed to be the ideal animal, the writer undertook to perform the experiments here reported. It was his purpose in this work to study the effect of the colon on bacteria introduced directly into it.

EXPERIMENTAL

Three dogs having the type of cecal fistula devised by Cowgill and Weinstein were used as the experimental animals. There was a minimum of leakage from the intestinal operative site; furthermore, the dogs were in an excellent state of nutrition throughout the course of the experiments.

The experiments were carried out under two different conditions. First, organisms were introduced into the colon when the dogs were on a diet consisting of lactose, bread and grains, and consequently harbored a large percentage of *L. acidophilus* in their intestines; and second, when the animals were on a strict meat diet and eliminated no demonstrable lactobacilli in their feces.

The organisms studied were *Ser. marcescens*, *S. lutea*, and *B. mycoides* (vegetative and spore forms). All of these were chosen because they could be identified easily in plate culture either by their color production or colony morphology. The organisms were grown on meat extract agar plates at their proper growth temperatures. The growth from two Petri plates was suspended in 5 c.c. physiological saline solution and instilled through the cecal fistula directly into the colon by means of a catheter and a 10 c.c. syringe. The animals were under continuous observation for a half hour after injection, to make certain that none of the instilled material leaked back through the fistula opening.

Both young (spore-free) and old (spored) cultures of *B. mycoides* were used. The absence or presence of spore forms was always checked by making a spore stain of the material to be introduced into the colon. When only spore forms were required, a suspension of a well matured culture of *B. mycoides* was heated at 80° C. for ten minutes before use. In culturing the feces for *B. mycoides*, cultures of both the heated and the unheated fecal emulsions were made.

At intervals of 24, 48, 72 and 96 hours after cecal injection, fecal material was obtained from each animal. One or more specimens of feces were emulsified in a small amount of physiological saline solution, and from one to two cubic centimeters of the suspension streaked on the proper media for identification of the organism sought. The cages in which the animals were kept were cleaned with soap and hot water immediately after each collection of feces, in order to eliminate possible contamination from this source.

EXPERIMENTS WITH DOGS HAVING A HIGH ACIDURIC INTESTINAL FLORA

The dogs were kept on a high carbohydrate diet for three weeks, at the end of which time they showed a high proportion of *L. acidophilus* in the feces; the bacterial injections were then made into the colon through the cecal fistula. Throughout this study, examinations were made every other day for the presence of the lactobacilli.

Ser. marcescens and *S. lutea* could at no time be recovered from feces of animals into which they had been injected by way of the cecum. Cultures of the fecal material made as early as 6 hours and as late as 96 hours after injection failed to reveal the presence of either of these organisms.

B. mycoides, however, gave entirely different results. When the vegetative cells were injected into the cecum

*Department of Bacteriology, Yale University.
Submitted *January 29, 1936.*

they were recovered in one dog as late as 48 hours after injection and in the other two animals even 72 hours after instillation. In no instance was it possible to recover them from the feces 96 hours after they had been introduced into the colon. When the unheated vegetative cells were employed, fecal suspensions showed the presence of *B. mycoides;* whereas, heated feces (10 minutes at 80° C.) never revealed the organism in culture. In other words, when vegetative *B. mycoides* cells were introduced directly into the colon by way of the cecal fistula only vegetative cells could be recovered from the feces.

Heated suspension of spore-containing cultures of *B. mycoides* instilled into the colon of the animals led to the recovery of the organism after 72 hours in two dogs and after 48 hours in the third animal. Cultures taken 96 hours after injection always failed to show the presence of the organism in the fecal material. In contrast to the results obtained following the injection of the vegetative cells, *B. mycoides* could always be cultured from the *heated* feces of the dogs which had been injected with the spores of this organism.

EXPERIMENTS WITH DOGS HAVING NO LACTOBACILLI IN THE INTESTINE

The dogs were kept on a purely meat diet until fecal examinations revealed the complete absence of *L. acidophilus.* The injection experiments were begun after an additional week on this diet.

The same results were obtained in this experiment with *Ser. marcescens, S. lutea* and the two forms of *B. mycoides* as in the experiments conducted when the dogs harbored an intestinal flora high in *L. acidophilus;* the first two organisms failed to appear in the feces at any time, while vegetative cells of *B. mycoides* appeared as vegetative forms, and the spores as spores in the fecal material.

DISCUSSION

Ample evidence has been obtained in this investigation to show that the large intestine of the dogs is capable of killing bacteria introduced directly into it. The cause of this lethal action is, of course, a debatable question.

Some objection may be raised to this work on the ground that no organism of purely intestinal origin was used. This procedure was necessary, it seems, since it would be impossible to detect the presence of common intestinal organisms introduced through the fistula in the feces because of the occurrence of the bacteria normally in the intestine. The use of some of the pathogenic intestinal organisms was contemplated, but this plan was soon discarded, because of the possibility of serious injury to the valuable experimental animals. However, experiments of this type are being contemplated.

Organisms Injected Into Colon

From the evidence obtained with *B. mycoides* it appears that, even though the organisms may pass through the large intestine alive, they do not multiply. Evidence for this statement is the fact that when vegetative cells of *B. mycoides* were injected into the colon only vegetative cells could be recovered from the feces, while the instillation of spores through the cecal opening always led to the recovery of spores in the feces of the dogs.

SUMMARY

Serratia marcescens and *Sarcina lutea* could not be recovered from the feces of animals into whose colon they were injected through a cecal fistula. This finding was the same whether the intestinal flora of the experimental animals was high or low in its *L. acidophilus* content.

B. mycoides could be recovered from the feces of dogs as late as 72 hours after injection; when vegetative cells were injected, only vegetative cells were recovered; whereas, when spores were introduced, spores were recovered. These findings were apparently independent of the status of the animals' natural intestinal flora.

The Nature of Peptic Ulcerations*
The Factor of Spasm

By

M. E. STEINBERG, M.S., M.D.
PORTLAND, OREGON

NUMEROUS investigators have been successful in producing ulcers of the jejunum by utilizing the Exalto (4) method of diverting the alkaline duodenal contents some distance below the gastrojejunal anastomosis. Steinberg (11) stripped the jejunum, anastomosed to the stomach, of about three-fourths of its longitudinal and circular muscle layers for a distance of ten centimeters (*Fig. 1*). *Such a procedure leaves* a narrow strip of muscle along the mesenteric border for the preservation of the blood supply to the jejunum. The above experiments were combined with an Exalto short-circuiting operation (Fig. 1). In the control experiments where the muscle layers are left intact an ulcer takes place in from 90 to 100 per cent

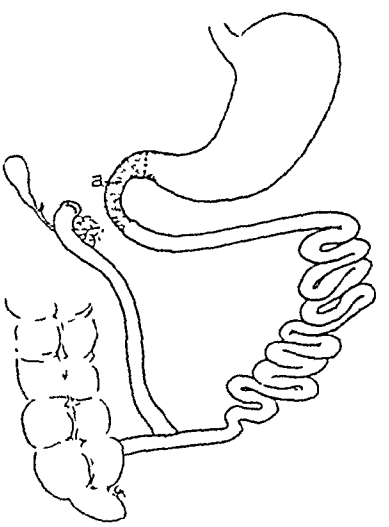

Fig. 1. The short-circuiting of the alkaline duodenal contents into the ileum. Muscle layer stripped for ten centimeters distal to the gastrojejunal anastomosis (a).

of the dogs operated by the Exalto method. Most of the ulcers are found one or two millimeters distal to the gastrojejunal anastomosis (Steinberg and Proffitt) (9).

Of sixteen dogs operated on with the Exalto short-circuiting operation, and with the muscle layers stripped, only three dogs developed typical ulcers of the jejunum one or two millimeters distal to the anastomosis. In five dogs ulcers were found ten centimeters distal to the gastrojejunal anastomosis, or exactly where the muscle layer began its normal course. This was the first time that ulcers were observed in this situation (Steinberg and Starr) (10) (Fig. 3).

*From the Physiology Department of the University of Oregon Medical School.
Submitted February 26, 1936.

Subsequent to the publication of the first two papers ten dogs were again operated according to the Exalto procedure, and again with the muscle layers of the jejunum stripped. In only one dog was an ulcer found at the gastrojejunal anastomosis, and in three dogs small ulcerations were found ten centimeters distal to the gastrojejunal anastomosis and, again, exactly where the muscle layer began its normal course.

It was impossible to explain the findings on the theory of an impact since these ulcers took place ten

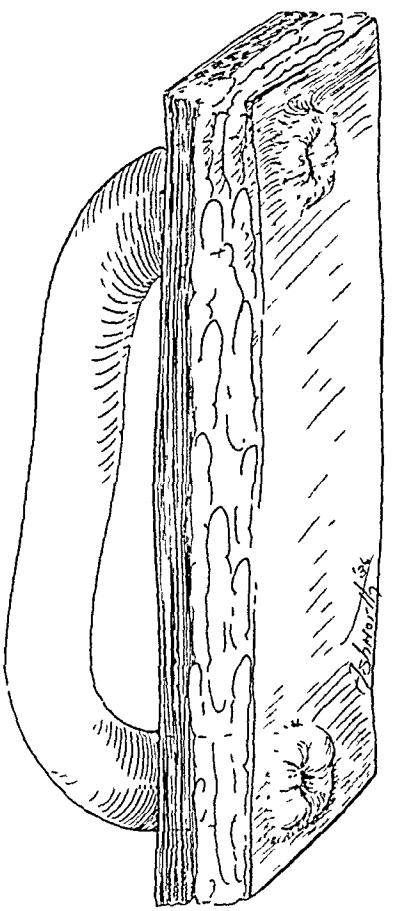

Fig. 2. A Thiry-Vella loop.

centimeters distal from where chyme is ejected by the pyloric sphincter. These ulcers which were never observed before were rather puzzling as to their nature. Inasmuch as no ulcers were observed where the muscle layers were stripped the spasm of the jejunum offered a plausible explanation. Apparently the stomach contents stagnate for a variable period of time in the part of the jejunum denuded of its muscle. When the contents reach the beginning of the jejunum with its in-

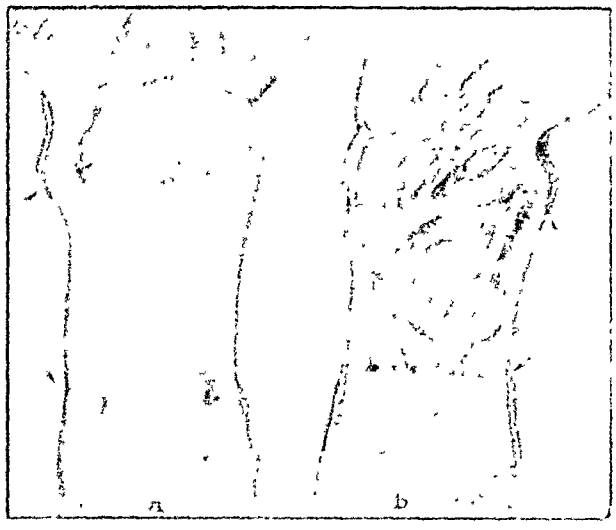

Fig. 3. A gastro-anastomosis (a) between the stomach and the jejunum with an Exalto short-circuiting operation. The area between the arrows shows where the muscle layer was stripped from the jejunum. A small ulcer near the pyloric valve and two chronic "kissing ulcers" exactly where the muscle layer begins its intact course, or about 10 cm. from the pyloric valve, are seen. On the peritoneal surface (b) of the same specimen the omentum covers the area in which the muscle is stripped.

tact layer of muscle a spasm takes place. Eventually the acid contents are neutralized and become acceptable to the distal jejunum.

In order to analyze the validity of the theory of spasm in relation to acid, we produced a Thiry-Vella loop (Fig. 2) about fifteen centimeters long and about fifteen centimeters distal to the duodenojejunal angle. After the recovery of the animals, a sponge, one centimeter long and about one-half of a centimeter wide, attached to a thread the length of the loop, was introduced into the proximal opening of the loop. (I. P. Quigley, W. H. Highstone and A. C. Ivy (7)). One hundred observations were carried out on five dogs. Some of the experiments were made with the sponge immersed in normal saline, while in others it was immersed in 0.15, 0.2, 0.3 and 0.4 per cent hydrochloric acid. One series of experiments with the sponge immersed in normal saline was immediately followed by another using the various strengths of hydrochloric acid. The results of these experiments, as carried out on five different loops, were remarkably consistent. As indicated by the Tables it is quite evident that the sponge immersed in hydrochloric acid produces a definite delay in its progress through the loop. The sponge immersed in 0.15, 0.2, 0.25 and 0.3 per cent hydrochloric acid brings about a more or less uniform delay in the progress of the sponge. On the other hand, three experiments with 0.4 per cent hydrochloric acid gave a rather bizarre result with either very prolonged delay or very rapid progress through the loop (Tables I and II).

It was observed that when the sponge immersed in saline was introduced into the proximal opening of the loop the dog offered no resistance and in most of the experiments was quiet. The secretion of the intestinal mucosa was not noticeable. On the other hand, in the experiments where the sponge was immersed in hydrochloric acid higher than 0.15 per cent, a copious secretion from the loop was produced. The protruding mucosa appeared pale and spastic. In a few experiments the dogs were restless, vomited and resisted the introduction of such a sponge. On certain occasions there was evidence that the sponge immersed in acid interrupted its normal course by a prolonged delay at some part of the loop.

It is impossible to minimize the importance of certain animal experiments (Steinberg and Proffitt) (9) since to a greater extent they represent a replica of the surgical procedures used in the treatment of gastroduodenal ulcerations. The primary ulcers of the jejunum are extremely rare. It is only after the gastro-enterostomy came into vogue that jejunal ulcers were beginning to be noticed with more frequency. A jejunal ulcer is being produced unwittingly with regularity in the patient by performing certain types of gastro-intestinal anastomoses. Some of the modern text books on surgery of the stomach and duodenum still recommend such operative procedures as the Roux anastomosis, the von Eiselsberg exclusion operation and also the Devine transection exclusion operation. One engaged in experimental surgery is able to produce typical postoperative jejunal ulcers in dogs by using the above mentioned procedures recommended to the surgeon as a cure for gastro-duodenal ulcerations, (Steinberg) (11). It is difficult to assume the presence of a constitutional predisposition in each one of these cases. It is more logical to attribute these jejunal ulcerations directly to the operative procedure. The various gastro-intestinal anastomoses in the dogs which produce typical jejunal ulcerations are therefore of great importance in elucidating some of the local factors responsible for the production of these lesions. These local factors do not exclude the importance of the constitutional predisposition, the disharmony of the vegetative nervous system or some form of an

endocrin imbalance. The experimental attack however, on the parasympathetic and sympathetic systems has not been conclusive. The only experiments which are under direct control are those which produce ulcers of the jejunum with a certain regularity by varying the anatomical and physiological relationships between the stomach and the jejunum. (Steinberg and Proffitt). The surgical procedures which give rise to postopera-

tive jejunal ulcerations are so closely related to the experimental procedures on the dog that by comparison there remains little doubt as to the true nature of the jejunal ulcerations in the human.

A vast amount of accumulated material on the experimental postoperative jejunal ulcerations is not

without any importance as to the nature of duodenal ulcers, as will be seen from the analysis of our experiments. Shay and Gershon-Cohen (8) in a very exhaustive study on the control of the pylorus have demonstrated that the addition of certain strengths of hydrochloric acid, depending on the original state of the secretion, have a definite relationship on the emptying time of the stomach. These investigators have noticed antral spasm and pylorus spasm from duodenal instillation of hydrochloric acid. Dragstedt and Palmer (3) operating under local anesthesia have noticed a marked contraction of the circular muscle of the duodenum after the exposure of the duodenal ulcer to 0.5 per cent hydrochloric acid. The patient complained of a severe cramp-like pain in the stomach.

The frequency of "kissing ulcers" of the duodenum has been reported by many clinicians. O. Bsteh (1) has reported thirty-two "kissing ulcers" out of one hundred and ten duodenal ulcers. Hoffman (5) noticed these ulcers in forty to fifty per cent of his cases, and Clairmont (2) in seventy-five per cent. According to my own experience the frequency of multiple ulcers is more common than previously observed. Some of the ulcers are in the state of healing and some are so small that they are either not recognized or are destroyed during the removal of a part of the duodenum with the stomach. This fact may explain the discrepancy in the observations of various surgeons.

Most of the ulcers of the duodenum have a typical location distal to the pylorus and separated from it only by a few millimeters. They are frequently found opposite each other, and for this reason named by Moynihan "kissing ulcers" (Fig. 4). In the further progress these ulcers may extend to the lesser or greater curvature of the duodenum. They may also coalesce and lose their original form and position. The progressive changes make it difficult to recognize the original location in many specimens on account of deformity and the scarring of the duodenum. A thorough microscopic examination of the removed part of the duodenum would be interesting and perhaps more convincing as to the nature and location of these lesions.

The characteristic localization of these ulcers in the same segment and on the anterior and posterior walls, opposite each other, is significant. A few of these ulcers were observed by myself in the experiments where the muscle of the jejunum was stripped, had the appearance of the "kissing ulcers" of the duodenum in the human (Fig. 4) and were found in the same circular segment of the jejunum (Fig. 3). It has been pointed out in several previous communications that these ulcers were at the segment of the jejunum where the muscle layer began its normal intact course, and exactly ten centimeters distal to the propelling force of the pylorus (Steinberg; Steinberg and Starr) (10). A mechanical trauma as of etiological importance can therefore definitely be excluded.

The experimental and clinical evidence, particularly as it concerns the localization of duodenal ulcers and jejunal ulcers, is suggestive of a certain theory of a local mechanism. While the search for some dominant cause in the diencephalon, or in some endocrin imbalance, or both, is highly interesting, it does not explain the typical location of many of these ulcers. So far there is no conclusive evidence of a definite pathological condition existing in the brain of individuals suffering from peptic ulcerations. Periodicity of the symptom complex in itself would make some pretense of a denial that there is a continuous pathological process in the diencephalon. One is therefore hardly justified to go farther than the observation that hypersecretion, hypermotility and hypertonicity of the stomach are closely related to the ulcer symptom complex and that these conditions are frequently found in the young type of individuals. It may also be stated that the ulcer symptom complex is frequently initiated in an environment of strain, worry and other forms of mental upsets.

Ulcers do not occur in the duodenum or jejunum because the complicated nervous mechanism which controls the motility, secretion and blood supply are constantly found in a certain equilibrium. These three factors are closely related to each other and influenced by the nervous system. A disturbance of one com-

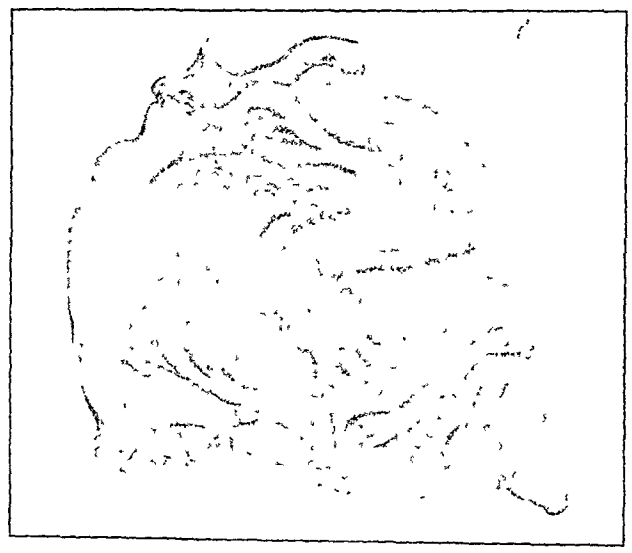

Fig. 4. Distal two-thirds of a stomach recently removed by the Author. "Kissing ulcers" in the duodenum which in their form and location closely resemble the experimental "kissing ulcers" in Fig. 3.

ponent influences the others. Clinically it is seen that there are definite cycles, crises and stimuli which are demonstrated in the functional disturbance of the stomach which finally lead to the formation of ulcer (Kalk) (6). Nor can one underestimate the importance of the equilibrium which also exists between the acid stomach and the alkaline duodenum or jejunum after a gastro-enterostomy. A gastro-intestinal anastomosis mobilizes the compensatory forces in order to maintain the necessary equilibrium between the stomach and jejunum. Under adverse conditions when the acidity of the stomach contents are abnormally high a jejunal ulcer or jejunitis takes place.

From the experimental work and clinical evidence there is sufficient support to consider hyperacidity, hypersecretion and spasm as a vicious circle. At times it is difficult to differentiate an acid gastritis or duodenitis from a duodenal ulcer. In fact a typical ulcer symptom complex may be present in the absence of a duodenal ulcer. A patient with a hyperirritable acid stomach under certain conditions is a candidate for a duodenal ulcer.

It is impossible to bring within the limits of a short paper the numerous theories advanced, or give credit to the important experimental work or to introduce much of the controversial material. Only factors under experimental control which closely parallel the clinical picture have been emphasized. It is because of these considerations that the gastric ulcer was left out, since thus far it does not seem to fit into this picture.

The experimental ulcers of the jejunum are produced with such ease by varying certain anatomical relationships between the stomach and the jejunum, based on the expected physiological changes, that a conception of the nature of these ulcerations becomes fully tangible (Steinberg and Proffitt).

A familiarity of these principles enables us to proceed "mutatis mutandis" with a rational medical and surgical treatment.

SUMMARY

In addition to a previous communication, ten more dogs were operated on according to the Exalto method and with the muscle of the jejunum stripped for an area of ten centimeters. Again, no ulcer took place where the muscles were stripped. In ten dogs operated on in this manner one ulcer was found one or two millimeters distal to the gastrojejunal anastomosis. In three dogs ulcers were found ten centimeters distal to the gastrojejunal anastomosis or exactly where the muscle area began its normal course. This interesting observation, reported elsewhere for the first time by the Author in another series of experiments, appears highly intriguing.

The progress of a sponge through a Thiry-Vella loop is definitely delayed when the sponge is immersed in hydrochloric acid ranging from 0.15 per cent to 0.3 per cent. The experiments with the Thiry-Vella loop are supportive of our previous contention that there is a close relationship between acidity and spasm of the jejunum and the etiology of the experimental ulcerations.

Emphasis is made upon the experiments of gastro-intestinal anastomosis which are in a greater part a replica of surgical procedures used in the treatment of peptic ulcerations. The typical jejunal ulcerations closely resemble the duodenal and postoperative ulcerations in the human.

No denial is made of the importance of the vegetative nervous system (diencephalon), and the endocrin glands or the constitutional type.

Emphasis has been made upon the equilibrium which normally exists between the stomach and duodenum and which may be disturbed in the individual with a certain constitutional predisposition and in an unfavorable environment. This initiates a local vicious circle of acid and spasm between the stomach and the duodenum or the jejunum in a gastro-enterostomy.

It is far from my intention to give these experiments and reflections a pretense of completeness and finality. It serves only to emphasize an interesting experimental observation and an attempt to explain the part which the local mechanism of the ulcer symptom complex plays as related to a general conception, as yet less tangible and so far experimentally, without conclusive evidence.

Studies in Absorption of Undigested Proteins in Human Beings

VI. The Absorption of Unaltered Protein from the Abnormal Gastro-Intestinal Tract

By

IRVING GRAY, M.D.

and

MATTHEW WALZER, M.D.

BROOKLYN, NEW YORK

IN earlier studies by Brunner, Sussman, Davidson and Walzer (1, 2), it was noted that, for unknown reasons, the rapidity of absorption of unaltered protein varied considerably in supposedly normal subjects. The findings in some patients with gastro-intestinal disease seemed to suggest a possible explanation for this phenomenon. It was noted that the absorption time in conditions which are usually accompanied by gastric hyperacidity seemed slower than in those in which hypoacidity usually exists. For this reason, an intensive study of the absorption phenomenon in abnormal cases seem warranted in order to obtain more definite information on the subject.

In the present investigation, a series of forty cases with functional or organic diseases of the gastro-intestinal tract were studied primarily for the purpose of determining whether a definite relationship exists between gastric acidity and the rate of absorption of unaltered protein following its oral administration. The majority of patients in this group had some form of disease of the upper digestive tract. The clinical diagnoses in these cases were arrived at as a result of operative procedures, X-ray examinations and laboratory studies. The gastric acidity was determined by a fractional gastric meal in approximately half the series and by a Boas-Ewald test meal in the remainder. In many instances, gastric analyses were repeated on several occasions in order to check abnormal findings, for, it is known that there may be variations in gastric acidity in the same individual depending upon such factors as the emptying time of the stomach, psychic disturbances, the amount of saliva swallowed, the type of test meal employed, regurgitation of duodenal contents, etc., (3, 4, 5, 6, 7, 8). The readings charted in Table I represent the acid values of gastric digestion determined in each case at the end of one hour following the ingestion of the test meal.

The technic for studying the absorption of unaltered protein is an immunologic one and is the same as that employed in previous studies with egg and fish antigens (9). Peanut was the protein chosen for investigation in the present series because a serum particularly suitable for the study of this antigen was available at the time.

Peanut was excluded from the diet of the subject for twenty-four hours preceding the experiment. The subject was then passively and locally sensitized on the forearm by the intracutaneous injections of .05 c.c. of a 1-10 dilution of "C" serum. This serum had been obtained from a patient who was extremely sensitive to peanut and who manifested a marked reaction to intracutaneous tests with this antigen in very high dilution. One or two days later, the subject reported early in the morning without breakfast for the peanut test meal. The latter consisted of a "milk" made by disolving 10 gms. of raw ground peanuts in 30 c.c. of water to which was added 1 gm. of sugar and .05 c.c. of oil of cloves. Shortly after the ingestion of this meal, a reaction developed at the sensitized site, which usually consisted of pruritis, erythema, and wheal formation. The onset of this reaction marked the entrance of the undigested peanut protein into the circulation.

The absorption time of each subject was measured from the time the test meal was taken to the first objective symptom noted at the sensitized site, namely, erythema or wheal. (See Table I). Although pruritis usually heralded the start of the local reaction, it was considered an unreliable starting point because it is a subjective symptom which cannot be detected by the investigator. A detailed description of the technic and local reaction have been presented in previous communications (9, 10).

Because atopic patients do not accept passive local sensitization normally and regularly (11), all patients with past, present or family histories of hay fever, asthma, or similar forms of atopy were excluded from this study.

For the purpose of analyzing the results obtained, the cases in this series were subdivided into four groups according to their acid values. Individuals who had a variation in free HCl between 20 and 30 degrees and a total acidity between 30 and 40 degrees were considered normal. A state of hyperacidity was considered present when the free HCl was constant at 40 degrees or over and the total acidity was constant over 60 degrees. Those in whom free HCl was constant at less than 10 degrees and the total acid was constant under 20 degrees were placed in the hypoacidity group. Individuals in whom no free HCl was present at any time comprised the anacidity group. The findings of Sagal, Marks and Kantor (12) in a study of 6679 test meals and those of Vanzant (13) and her co-workers who analyzed 3746 records of the Mayo Clinic, justify this broad classification of cases into four groups, according to the degree of gastric acidity.

The results of the studies on protein absorption obtained on the nine patients in this series who have normal gastric acidity values have been grouped in Table II. The shortest absorption time among them

SECTION III—*Nutrition*

The Chemical Nature of the Anti-Anemic Principle*

By

JULIUS SCHULTZ, B.S.

ANN ARBOR, MICHIGAN

THE chemical nature of any physiologically active substance is of particular interest to the biological chemist in that it leads to the determination of the structure of the reactive material. And the work of the biological chemist will not have been completed before he has related the structure of such material to its physiological reaction (40).

Before the chemical nature of any substance can be accurately studied, its isolation in a pure state is of prime importance. In truth, however, a review of the literature offers rather discouraging results in this respect; for no one has laid claim to the chemical individuality of any product yet prepared. Nevertheless, enough negative proof has been offered to serve as a basis for much speculation, which, though doubted even by its own author, provides a working ground for further investigation.

The work on the isolation of the active principle was begun after Minot and Murphy (1), induced by the provocative work of Whipple (2), showed that liver was a rich source of anti-anemic principle.

Before entering into the discussion of this principle, it is important first to obtain a conception of the exact physiological reaction produced by the factor, that is indicative of its presence in a product.

A small percentage (1% in normal adult) of the circulating blood cells contain a material that shows a bluish net work when stained with brilliant cresyl blue. Because of this property these cells have been called reticulocytes. The reticulocytes arise from the bone marrow and eventually become red blood cells (3).

It is the remarkable increase in the number of these cells as effected by the anti-anemic principle that has been the basis for determining the presence of the factor in its various sources. Figure 1 shows a typical reticulocytic response.

Castle and Minot (3) have recently described and interpreted this reticulocytic response to anti-anemic material. Their study is at this time especially important because of the need of a more quantitative basis of evaluating products said to be capable of such hematopoietic activity. Furthermore, the lack of a more available biological test makes it more necessary.

The first attempt at fractionation was systematically undertaken by Cohn and his collaborators (4). Such an investigation required a chemist to do the isolation work, a doctor and his technicians to study the responses, and above all, enough patients with pernicious anemia to test out the various products. Hence the first report was the work of E. J. Cohn, G. R. Minot, J. F. Fulton, H. F. Ulrichs, F. S. Sargeant and W. P. Murphy. And yet the product remains a mystery.

They proceeded finally as follows (5): fresh minced beef liver was directly made acid and filtered. The

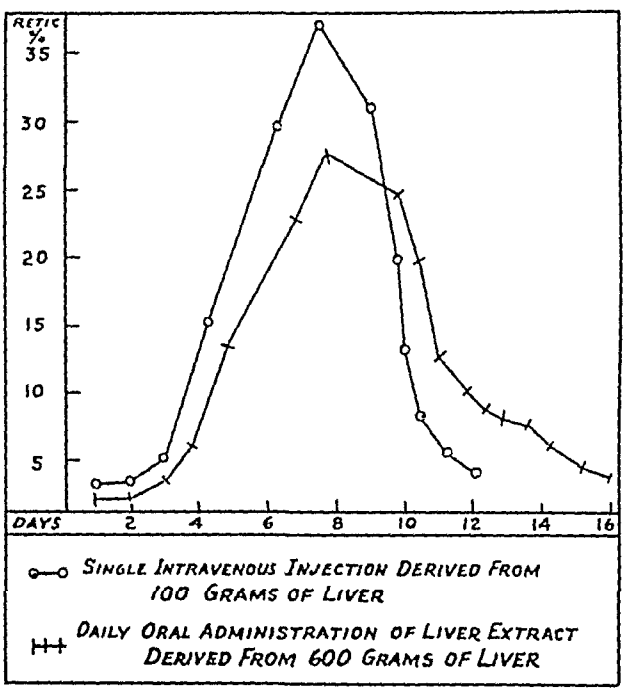

Fig. 1

filtrate (A) was heated and the coagulate proteins (C) separated. After the resulting solution (D) was concentrated, it was found to be clinically active. The potency was not diminished after extracting D with ether and 95% alcohol. The active residue remaining after the alcohol extraction was called G and was immediately put on the market as Eli Lilly's "343."

This fraction was further purified by precipitating the carbohydrates with an alkaline solution of lead acetate. After proving the filtrate, 0, to be active, it

ponent influences the others. Clinically it is seen that there are definite cycles, crises and stimuli which are demonstrated in the functional disturbance of the stomach which finally lead to the formation of ulcer (Kalk) (6). Nor can one underestimate the importance of the equilibrium which also exists between the acid stomach and the alkaline duodenum or jejunum after a gastro-enterostomy. A gastro-intestinal anastomosis mobilizes the compensatory forces in order to maintain the necessary equilibrium between the stomach and jejunum. Under adverse conditions when the acidity of the stomach contents are abnormally high a jejunal ulcer or jejunitis takes place.

From the experimental work and clinical evidence there is sufficient support to consider hyperacidity, hypersecretion and spasm as a vicious circle. At times it is difficult to differentiate an acid gastritis or duodenitis from a duodenal ulcer. In fact a typical ulcer symptom complex may be present in the absence of a duodenal ulcer. A patient with a hyperirritable acid stomach under certain conditions is a candidate for a duodenal ulcer.

It is impossible to bring within the limits of a short paper the numerous theories advanced, or give credit to the important experimental work or to introduce much of the controversial material. Only factors under experimental control which closely parallel the clinical picture have been emphasized. It is because of these considerations that the gastric ulcer was left out, since thus far it does not seem to fit into this picture.

The experimental ulcers of the jejunum are produced with such ease by varying certain anatomical relationships between the stomach and the jejunum, based on the expected physiological changes, that a conception of the nature of these ulcerations becomes fully tangible (Steinberg and Proffitt).

A familiarity of these principles enables us to proceed "mutatis mutandis" with a rational medical and surgical treatment.

SUMMARY

In addition to a previous communication, ten more dogs were operated on according to the Exalto method and with the muscle of the jejunum stripped for an area of ten centimeters. Again, no ulcer took place where the muscles were stripped. In ten dogs operated on in this manner one ulcer was found one or two millimeters distal to the gastrojejunal anastomosis. In three dogs ulcers were found ten centimeters distal to the gastrojejunal anastomosis or exactly where the muscle area began its normal course. This interesting observation, reported elsewhere for the first time by the Author in another series of experiments, appears highly intriguing.

The progress of a sponge through a Thiry-Vella loop is definitely delayed when the sponge is immersed in hydrochloric acid ranging from 0.15 per cent to 0.3 per cent. The experiments with the Thiry-Vella loop are supportive of our previous contention that there is a close relationship between acidity and spasm of the jejunum and the etiology of the experimental ulcerations.

Emphasis is made upon the experiments of gastro-intestinal anastomosis which are in a greater part a replica of surgical procedures used in the treatment of peptic ulcerations. The typical jejunal ulcerations closely resemble the duodenal and postoperative ulcerations in the human.

No denial is made of the importance of the vegetative nervous system (diencephalon), and the endocrin glands or the constitutional type.

Emphasis has been made upon the equilibrium which normally exists between the stomach and duodenum and which may be disturbed in the individual with a certain constitutional predisposition and in an unfavorable environment. This initiates a local vicious circle of acid and spasm between the stomach and the duodenum or the jejunum in a gastro-enterostomy.

It is far from my intention to give these experiments and reflections a pretense of completeness and finality. It serves only to emphasize an interesting experimental observation and an attempt to explain the part which the local mechanism of the ulcer symptom complex plays as related to a general conception, as yet less tangible and so far experimentally, without conclusive evidence.

phuric acid with mercuric sulphate in presence of alcohol and ether.

Carbohydrates were considered to have been eliminated by Cohn, Minot and Murphy (9, 10) by the precipitation with lead acetate, after which the solution gave a negative Molish. Sturgis, *et al*, found that glucosamine could not be present because it would be held back by permutit, through which the material containing the active principle had been passed. No investigators have intimated the possibility of the anti-anemic principle's containing carbohydrate except Dakin, whose work will be taken up in detail later.

f	11	6	6	6	6

By the method of Fürth and Schwartz (8) these investigators found that the extracts could be divided into two parts with phosphotungstic acid:

1. Precipitated by phosphotungstic acid
2. Not precipitated by phosphotungstic acid

Because no ether liver extracts have shown any anti-anemic potency, everyone is in agreement that the principle is not lipid in nature.

The possibility of purine bases, polypeptids and nitrogenous base were considered by Cohn and his collaborators (10). Because an active solution gave no precipitate with trichloroacetic acid, or tungstic acid, no increase in amino nitrogen on hydrolysis and no biuret reaction, they discarded the possibility of it being a polypeptid. Felix and Frühwein (13) also came to this conclusion, as did Reiman, *et al*, (35).

Although slightly soluble in 95% alcohol, the active material, regenerated from phosphotungstates, has been dissolved in it (10) and found active. The undissolved proteoses, peptones, and polypeptids were inactive. On further concentration with alcohol, active material was precipitated which contained largely nitrogenous bases.

Purine bases were removed and no precipitate was obtained with flavianic acid in neutral solution. That nitrogenous bases were still present was confirmed by the fact that the solution still gave precipitates with magnesium acetate.

The material precipitated from the alcohol, freed of protein, carbohydrates, lipids, proteoses, peptones and polypeptids which Cohn and his co-workers called "I.E." was the basis of all further investigations by this group (10).

With various mixtures of alcohol, water and ether, they succeeded in separating hematopoietically active fractions free of phosphorus, iron and sulphur compounds. In addition, it also gave negative Molish, biuret, Pettenffoffer, Millons, nitroprusside, and diacetyl reactions; furthermore, tryptophane, tryosine, arginine, cystine and creatine were absent. No precipitates were produced with trichloroacetic, picric, picrolanic or flavianic acids. However, it not only still gave precipitates with phosphotungstic acid and mercuric sulphate in acid solution, but also with gold and platinum chlorides and silver nitrate. Two grams of this substance produced a maximal reticulocytic response.

The final proof of the school of Cohn which led to confirmation by pure negative evidence that the active principle was of the nature of a nitrogenous base, was based on the following observation:

By treating the product just mentioned with ether and alcohol and later repeatedly recrystallizing it with mercuric sulphate, they removed a crystalline substance whose nitrogen was all alpha-amino-N. Formol titration showed that the carboxyl groups were equal in number to amino groups. But this crystalline substance was *inert* clinically.

Nevertheless, by extracting the precipitate containing mercury and the active principle with various mixtures of alcohol, ether and water, they succeeded in producing a product which no longer contained appreciable amounts of alpha-amino-N. It also showed no increase in carboxyl groups when treated with formaldehyde. This substance was highly potent.

Thus the inactive crystalline substance showed amino acid properties, but the active potent material showed no such properties; and as a conclusion the investigators claimed the active principle "gave strong evidence of being a nitrogenous base of the secondary or tertiary amine type." In addition, since the nitrogen in the purest fractions never exceeded 10.8%, purine and pyrimidine bases could be excluded, but not rings of the pyrrole or pyridine type.

At about this time (1930) Randolph West and Marion Howe (14) thought they had isolated the anti-anemic principle in crystalline form as the quinine salt of beta-hydroxyglutamic acid. It was precipitated from the acid hydrolysate of a product prepared as follows:

What remained of an aqueous solution of a commercial liver extract after it had been extracted in turn by saturated picric acid and a mixture of butyl alcohol and ether, was precipitated with fresh lead hydroxide, then with lead acetate; after removing the heavy metals, the solution was again precipitated with phosphotungstic acid with which the active material came down as the tungstate. Upon regeneration and removal of tungstate the solution was concentrated and precipitated with absolute alcohol. It was from the hydrolysate of this precipitate that hydroxyglutamic acid was isolated. Later Dakin and West (16) also isolated

hydroxyproline and concluded that the anti-anemic principle was made up of these two amino acids.

Still later, however, West and Howe withdrew their claim (17).

Here is seen the obvious necessity of a more practical test for active products.

In 1933 Felix and Frühwein (13) who have already been quoted, also found that the anti-anemic principle was not a peptid. Furthermore, they reported that no fraction less than 7% N was active and that their product gave them a negative biuret, a positive diazo, Sakaguchi and ninhydrin, but that they only obtained a positive Millons with mercuric sulphate precipitates. In further agreement with Cohn and his school, these workers found neither phosphorus nor sulphur. Reiman (35) and his co-workers had at this time found that the active principle in Heprakton was not broken down by the enzymes, erepsin, pepsin or trypsin, and concluded also that it must be of the nature of an amine rather than a polypeptid.

Joe Erdos has obtained a substance by digestion with sulphuric acid at various temperatures and subsequent purification which has a total nitrogen of 4.414% and shows on hydrolysis an increase in amino nitrogen of 300% (51). He prepared this as the silver salt whose molecular weight was determined as $C_{27}H_{72}N_{10}S_3P_2Ag_2$. But since he has used dogs to test the hematopoietic activity of his product, its relation to the antipernicious anemic factor is questionable; the more so because it has been shown that fractional parts of anti-anemic material may be active in animals, but that only the combination of the fractions is effective in humans (50).

COMPOSITION OF SILVER SALT

C —	78. %	Amino-N —	.86%
H —	7.2%	S —	.94%
O —	5.74%	P —	6.2%
N —	1.2%	Ag —	3.7%

He has calculated 18 amino acids from N content and believes there are three free carboxyl groups. His product gave a positive biuret and no precipitate with sulfosalycylic acid.

Before entering into the discussion of the most recent work on the anti-anemic principle, some insight as to its chemical nature may be obtained in reviewing the work on the physiology and pathology of the substance.

The most thorough review of this phase of pernicious anemia has been offered by Karl Singer (18) and Klumpp and Koletsky (19).

Work in this field was started by the brilliant investigation of W. B. Castle (20) on the relation between gastric secretion and pernicious anemia, which revealed "that in contrast to conditions within the stomach of the pernicious anemia patient, there is produced during digestion of beef muscle within the normal stomach some substance capable of promptly relieving anemia, similar in this respect to the substance found in liver." Following this discovery, he developed in a series of papers (21-23) a theory which runs as follows:

Because beef muscle and gastric juice are each ineffective as anti-anemic factors when fed to patients with pernicious anemia, and because, when previously allowed to interact and then fed, they are hemotopoietically active, there must be two factors that produce an anti-anemic principle that is related to the material found in the liver.

The one is an *extrinsic* factor present in beef muscle, and the other an *intrinsic* factor found in gastric juice. Thus:

EXTRINSIC FACTOR + INTRINSIC FACTOR = ANTI-ANEMIC PRODUCT

Castle's now classical *in vitro* synthesis of active principle consisted in heating raw beef muscle and fasting normal gastric juice and bringing the solution to the proper reaction with HCl.

According to Castle *et al* (21) the intrinsic factor is organic in nature, is destroyed when heated at temperatures between 70° and 80° for one-half hour, or 44.5° for four days, and that it is probably an enzyme.

Of the extrinsic factor he found that isoelectric precipitation (21) of beef muscle after extraction with ether produced a substance able to substitute for beef muscle. In addition, the fact that acid hydrolysis of liver extract until the anti-anemic factor was destroyed, does not destroy extrinsic factor; the fact that the substance in autolyzed yeast is capable of resisting autoclaving for five hours at fifteen pounds pressure; the fact that extrinsic factor is soluble in 80% alcohol and finally, the fact that it is present in leached casein, wheat glutelin and in animal or yeast nucleic acid, led Castle and Strauss (24) to suggest Vitamin B_2 as the extrinsic factor. However, as the literature began to fill up with reports disproving this, Castle himself (25) doubted the relation. Among the first to report these results were Wills (26), Lassen and Lassen (28) and Dühl and Kühnau (27). Wills (26) showed that Vitamin B_2 (of egg white) incubated with gastric juice was inactive hematopoietically. Recently Vitamin C has been found to be absent in an active product (38).

In 1932 Klein and Wilkinson undertook the study of the extrinsic and intrinsic factors and after a series of investigations (29-32), they finally concluded that the intrinsic factor was an enzyme (32) which they had named "hemopoietin" (29); and that the substance produced by the action of this enzyme on extrinsic factor was the same as the active principle found in liver. They then wrote the reaction:

ENZYME + SUBSTRATE = PRODUCT or
HEMOPOIETIN + EXTRINSIC FACTOR
ACTIVE PRINCIPLE IN LIVER

In these investigations Klein and Wilkinson first found that hemopoietin could not be extracted from stomachs by methods used to isolate active material from liver; second, that it came down with the protein fractions when precipitated from alcohol; and third, that it was heat labile. Because of these observations they decided it was entirely different in nature from the active principle in liver and changed their methods of isolation accordingly (29).

Hence, they used a special high compression apparatus (29) to express the juice of stomach tissue.

On adding alcohol to an acid solution of the expressed juice, a precipitate was obtained which contained hemopoietin and pepsin. The filtrate contained neither of these and was clinically inactive. On treating the precipitate with .1N HCl to a pH-2, it was found that the activity of hemopoietin was destroyed but peptic activity remained. Adding acetone to the .1N HCl solution also inactivated hemopoietin. But when the

acid solution was brought to pH 6.2 and precipitated with alcohol, the precipitate, though it was practically free of pepsin, was hemopoietically active.

The significance of this preparation lies in the fact that the gastric juice factor had been proven to be both different in nature to pepsin and independent of pepsin in its action.

By virtue of this preparation and further study, Klein and Wilkinson showed hemopoietin to be enzymic in nature. They listed the following reasons (32):

a. Expressed from gastric juice.
b. Invariable association of pernicious anemia with deficient enzyme secretion.
c. Difficulty of extraction of hemopoietin from tissues.
d. Its apparent destruction by prolonged action of pepsin and trypsin.
e. Its association with the protein fraction of stomach press juice.
f. Its thermolability and sensitivity to chemical treatment.
g. Its instability.
h. The fact that the reaction of a thermolabile substance on a substrate produced a thermostable substance. At the same time they tried to show that the product of this enzyme reaction was the same as the active principle in liver. The following tabulation best summarizes their results:

TABLE—Klein and Wilkinson (32)

Hemopoietin	Active principle in liver	Product of hemopoietin and beef
1. ppt. with proteins	not ppt. with proteins	not ppt. with proteins
2. positive protein reactions	negative protein color reactions	negative protein color reactions
3. Soluble in water	Soluble in 70% alcohol	Soluble in 70% alcohol
Insoluble in 70% alcohol	Soluble in 70% alcohol	Soluble in 70% alcohol
Thermolabile	Thermostable	Thermostable
Inactivated by acetone	Unaffected by acetone	Unaffected by acetone

As fine as these relations look, Castle (25) claims that since these authors prepared their product of enzyme digestion of beef muscle at a temperature of 37.5° and then only heated to 60-65°, they had no right to claim its thermostability equal to that of the anti-anemic principle in liver. He stated that active principle in liver is inactivated by heat only after:

1. Boiling for 5 minutes.
2. Heating to 10-80° for ½ hour, or
3. 40° for 3 days.

Castle, however, believes that Wilkinson and Klein may have been studying a precursor of the active principle (25). This equation would be:

HEMOPOIETIN + EXTRINSIC FACTOR = PRECURSOR TO ACTIVE PRINCIPLE

In support of their enzyme hypothesis Klein and Wilkinson cited the work of Helmer, Foutes and Zerfas (33).

After ultra-filtering gastric juice these investigators found that both filtrate and residue were inactive. But if the gastric juice were concentrated *in vacuo* it was found to contain anti-anemic activity. Also, when this concentrated gastric juice was ultrafiltrated, the material unable to pass through the filter was found to be inactive while the filtrate contained a substance capable of producing a reticulocytic response. In addition, the part of *fresh gastric juice* unable to pass through the ultrafilter was concentrated *in vacuo*, and it was found to contain the active principle, while the same treatment of the filtrate failed to produce active product.

The significance of this experiment may be seen more easily in the following diagram:

FRESH GASTRIC JUICE

Ultra-Filtered		*Concentrated in Vacuo (Active)*	
Residue (Inactive)	Filtrate (Inactive)	Ultra-Filtered Residue Inert	Filtrate Active
Concentrated in Vacuo	*Concentrated in Vacuo*		
Product is Active	Product Inactive		

To explain the part of this picture that strengthens the enzyme theory:

H = enzyme
B = substrate
A = active principle

Filtrate thus inactive in concentration

Conclusion:

H + B (Large molecule) *concentrated in vacuo* = A (Small molecule)

Greenspon has recently offered an entirely different conception from that of Castle and of Wilkinson and Klein. He believes that the external factor is not a source of potentially active anti-anemic substance, but that it is merely effective in blocking the antagonistic action of pepsin on the active principle in the gastric juice (45). Thus:

anti-anemic principle + pepsin + protein gastric juice (Inactive) = anti-anemic principle (Active) + protein-pepsin complex

In support of his view he showed that pepsinized ventriculin and pepsinized gastric juice are each ineffective, but when these substances are not subjected to the action of pepsin they are clinically active. On this basis and on the basis of the protein's absorbing the pepsin, he re-interpreted Castle's experiments and the action of the stomach extract. The work of Wilkinson and Klein (29, 30) he refuted by saying that the differences in thermolability between the stomach "enzyme" and liver principle are due merely to the impurities in their mixtures. Greenspon, thus, does not believe that the stomach and liver principles are different. As stated above, Castle did not believe that Klein and Wilkinson were dealing with the anti-anemic principle of the liver, but he did believe that it might be a precursor. Finally, Dr. Greenspon failed to explain the experiments of Foutes, Helmer and Zerfas which Klein and Wilkinson had used to support their hypothesis.

This question of whether the principle of gastric juice is itself the anti-anemic principle, whether it is a hormone (46) or whether it is an enzyme can only

be definitely settled by determining the exact chemical constitution of the anti-anemic principle.

This leads us to the work of Dakin whose speculative conclusions, though based on negative experimental results, now become increasingly more significant.

One does not have to go far off the trail of the work done on the active principle of pernicious anemia to trace back the possible steps that reviewers in the future may use to show how Dakin may have arrived at his speculation. I am presenting this both to make it easier to appreciate Dakin's work and to see some positive truth in his negative results.

After Minot in 1926 pointed to the liver as a source of the anti-anemic principle, Castle in 1929 brought our attention to an activity in the stomach as a step in its production. By 1933, Sturgis and Isaacs (37) had produced a desiccated stomach preparation containing the anti-anemic principle. In 1934, Wilkinson and Klein (32) showed that gastric mucosa was also a source of an anti-anemic principle. In addition, Helmer, Foutes and Zerfas (33) had shown that gastric juice contained both the supposed enzyme and a potentially active material.

And now the work of Dakin has led him to the point of saying, "It is obvious that a substance of the chemical nature (hexosamine polypeptid) of the substance under question (active principle) might well be considered as having intimate relation with a rather indefinite group of substances classified as mucins . . ."

Since his is the most recent work on the subject and dares to go further than any other work so far presented on the chemical nature of the anti-anemic principle, it will be of interest to see exactly how Dakin, on purely negative evidence, led up to the belief that glucosamine, a possible breakdown product of a hypothetical stomach mucin, may be the structural unit of the anti-anemic principle. It must be remembered that Dakin (6) lays no claim to chemical individuality of any of his products.

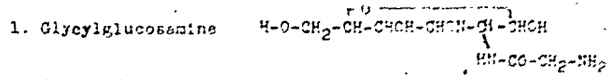
All of the following is from Dakin and West (6):

The product studied was that obtained by repeated salting out with magnesium sulphate of active material purified with alcoholic calcium acetate, Reinecke's acid, and repeated salting out with ammonium sulphate. Its analysis is as follows:

	Percent
Carbon	50. -51.4
Hydrogen	7.0- 7.2
Nitrogen	15.2-15.4
Amino Nitrogen (Van Slyke)	.4- .5
Amino Nitrogen (after hydrolysis)	10.6-10.8
Sp. Rotation in Degrees	95 - 106

After hydrolysis the amino nitrogen increased more than twenty-fold.

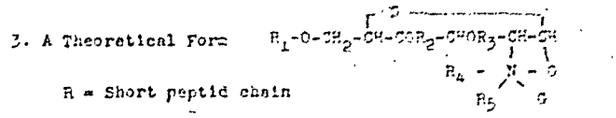
Amino Acids Present After Hydrolysis



Histidine	.1 (trace)
Arginine	14
Lysine	5
Leucine	15
Hydroxyproline	10-14
A monoaminodicarboxylic acid fraction as Ca salts	41-45
50% of which Aspartic acid	
5% of which Glycine	
15% of which Aminohexose	

From the hydrolysate there was obtained an aminohexose which appeared to be like glucosamine rather than the isomeric forms, isoglucosamine or fructazine because:

1. It gave a phenylglucosazine on treatment with phenylhydrazine.
2. It formed pyrrole derivatives on condensation with acetyl acetone, which is the basis of the quantitative method for glucosamine.
3. Ammonia was liberated in treatment with alkali, which is characteristic of the glucosamine type of compounds. And chondrosamine was absent.



Though the product gave a positive Molish reaction, Dakin found that glucosamine polypeptids behave similarly. An atypical biuret like that of the product was obtained by synthetic glucosamine. He offered three possible types of structures to the glucosamine.

1. Glycylglucosamine

2. Anhydride Form

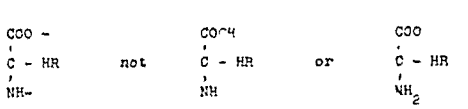
3. A Theoretical Form

R = Short peptid chain

Properties	NH_2N	Fehlinge	Biuret	OH groups
1.	50%	x	?	many
2.	0	-	green	many
3	0		?	none
4. Active product	(very little due to arginine)	-	green	many

Because of this relation the anhydride was assigned to the possible chemical structure of the active principle.

Laying grounds for future investigation Dakin discussed the possibility of the polymerization of the hexosamine; that is a proteose, peptone or polysaccharides.



"Whether the aminohexose is united in polysaccharide form as the chitobiose obtained from chitin by Bergmann, Zerfas and Silberkeit (34) remains unsolved. Preliminary experiments have shown that acetolysis of the substance gives unsatisfactory results because while an acytated compound readily soluble in chloroform is obtained, there are still groups attached to the glucosamine skeleton."

Because it is not precipitated by trichloroacetic acid, ferrocyanic and, or rufianic acid, but is precipitated by tannic acid, it would be classed as a peptone. But because it is easily salted out by $(NH_4)_2SO_4$ makes it a proteose. However, by using synthetic products again, he claimed that peptids of three or four amino groups are known which can be easily salted out, thus "making this distinction arbitrary."

In addition Dakin obtained a red color with alkaline picric acid which indicates the diketopiperazine group, but since glucosamine gives precisely the same reaction, he believed the test to be "within value under the circumstances."

He claimed also that a positive diazo Pauly reaction obtained from a virtually free histidine product was due to glucosamine. Finally, complete inactivation was brought about by boiling with $(NH_4)_2SO_4$. "This can be expected of a substance like a glucosamine poly-

peptid." As for the other chemical properties, he found that action of cold alkali brought about complete racemation of amino acid groups, as well as a marked reduction in specific rotation of reactive product. As a result he assigned the internally bound forms to alpha amino and adjacent carboxyl group. Thus:

These results, as negative as they are, do point to the active principle being a polymer with a glucosamine unit, even though glucosamine has itself not been isolated. Its isolation would certainly be welcomed.

The more definite work of Dakin consisted in showing the molecular weight to be a multiple of 570 by the percentage Reineckate, of 1430 by titratable acidity, or of 2920 by percentage of lysine. Moreover, he found that it can be decomposed by pepsin and erepsin and showed the absence of purine and pyrimidine bases. Reiman, Senek and Fritsch (35) claimed that their active material was not attacked by pepsin, trypsin, or erepsin. It may be that they did not permit it to act long enough; for on comparison of the data with Dakin's, we see that the German workers only let their enzyme act for 48 hours (Fig. 4).

It is not hard to see how this work of Dakin's is entirely out of harmony with the work done before 1935. For instance, Cohn and his school, it should be recalled, obtained precipitates with picric, picrolonic, and flavianic acids while Dakin did not; and that Cohn got a negative biuret, negative Molish, and negative diacetyl reactions. Furthermore, Cohn and his associates, Felix and Frühwein and Reiman (*et al*) were rather certain the anti-anemic principle was not peptid in nature.

SUMMARY

To summarize the work done, all that can be said is that before 1935, most of the sentiment rested with the anti-anemic principle's being a nitrogenous base while Dakin has since shown us the possibility of a glucosamine peptid perhaps derived from a mucin-like substance.

Further work on the chemical nature of the anti-anemic principle, greatly retarded by the present methods of testing products, will surely go ahead much faster should a more convenient method be developed. In this respect K. Singer has recently suggested the use of rats (36). In addition, after making a complete survey of the literature on the bioassay of anti-anemic material, Jacobson (47) has himself offered a guinea pig technique (48) which proved to be most promising. Crude extracts of fresh human livers assayed by him yielded results that corresponded beautifully with the state of the patient in pernicious anemia. However, his work has not yet been confirmed and some who have tried it deny its usefulness (49).

NOTE: The author is aware of the work recently done on the hematopoietic action of phosphoric acid compounds of creatine and creatinin by U. Syzuki, W. Hakahara and F. Inukai; however, since this work was done on rabbits we cannot use it as such in discussing the chemical nature of *anti-anemic principle* (39).

SECTION IV—*Roentgenology*

Functional Changes of the Vermiform Appendix Producing Diverticular Sacculation of the Spastically Contracted Organ

By

A. GALAMBOS, M.D.*
NEW YORK, NEW YORK

THE case reported here represents an unusual functional anomaly of the vermiform appendix, as evidenced and demonstrated by means of its Roentgenological aspect. The functional changes as exhibited on the films, are not permanent, nor uniform; they are rather shifty in character. The appendiceal picture is unusual, somewhat grotesque, as regards its morphological appearance. Although the films are not alike, nevertheless two characteristics are readily demonstrable on each of them, viz.: a *spastic contraction* of some and a *circumscribed dilatation* of other segments of the appendicular lumen. These constituents, alternating over the various segments, are readily discernible on each of the films.

In the properly exposed right iliac fossa, the vermiform appendix is well visualized with a narrow, spastically contracted, nearly obliterated lumen. The configuration and position of the appendix vary on the different exposures, proving a free moveability and contractility, i.e. a proper physiological behaviour. From a pea to a bean sized sacculation, a diverticular or cyst-like sudden expansion of the lumen was demonstrated on each of the films. The size, the location and the shape of the sacculation were not strictly uniform. It was located on some of the films closer to the proximal, on some others again closer to the distal end of that organ and extended in different directions, on some of the exposures upward, on others again, downward or along the course of the lumen.

CASE REPORT

A. S., 32 years of age, white, female, singer, first seen at my office on the 11th of December, 1928. The chief complaints referred to certain abdominal pain, with a localization in the left upper quadrant. Painful attacks recurred at gradually increasing frequency, in intervals, since the last five years. In the early stage painful periods were followed by 8 or 9 months' free intervals, in contrast to the more recent state when painful and free periods alternated with each other in nearly equal time intervals (2 or 3 weeks). Patient was during the first examination for five days in the midst of a painful period. The pain, as described, was rather sharp, continuous, still never severe enough to confine patient to bed. Maximal pain occurred a few hours after meals. Before and immediately after meals patient felt relatively free. Other data of history were of no significance.

Within her memory, patient has felt very nervous, a condition, which has been aggravated since the onset of the present ailment. She felt trembling in her body, especially during painful abdominal attacks, and was highly irritable, tense.

The physical examination revealed a circumscribed tender area above the umbilical region, over the left side, below the splenic flexure, the tender area being of a higher location than encountered in gastric ulcers. The appendicular, the gall bladder, and the pyloric regions failed to show pressure tenderness or other signs of any pathology.

X-ray examination of the gastro-intestinal tract revealed a perfectly normal stomach and duodenum. No direct or indirect signs, or even suggestive symptoms of a peptic ulcer were detected. The descending colon showed a very marked spasm, throughout its length, the contracted lumen being even narrower than an average appendicular lumen. No transverse rugal or haustral markings were visible. The appendix showed spastic contraction with diverticular sacculation of its center, as above mentioned. On repeated examination, the spasm in the colon changed, with a simultaneous shift in the appendicular configuration. After a few months' rest, combined with psychic and medical treatment, condition of the patient improved to a great extent, pain had disappeared entirely and in this improved mental and physical state, a re-examination performed, revealed an appendix, perfectly normal in every respect, with a uniform and equally patent lumen, without any sign of spasm or sacculation. The colon was similarly normal.

Patient, after years, has been in good health.

THE SPASM: ITS SIGNIFICANCE

The complaints, especially the post-cibal, left-sided, circumscribed pain were grossly suggestive of a peptic ulcer of the stomach. Closer examination and the X-ray study, however, were not corroborative. "Mucous

Submitted January 6, 1936.

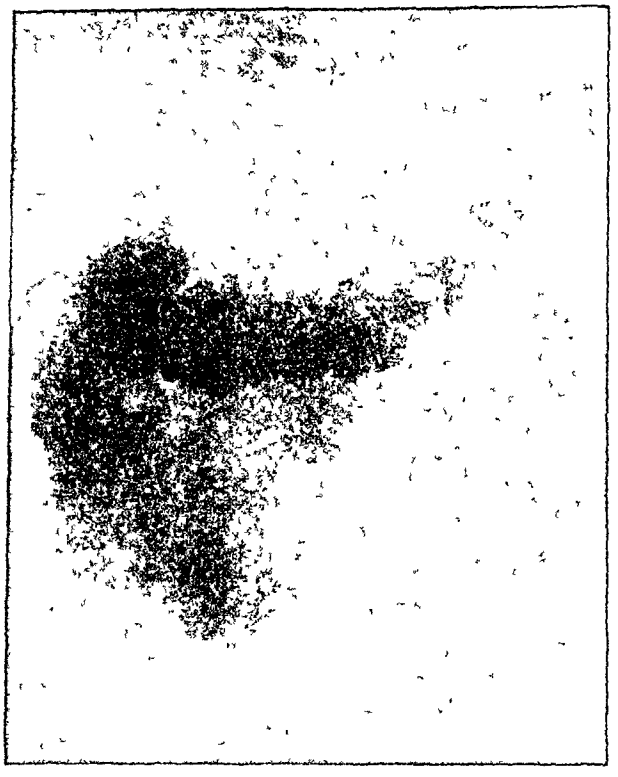

Fig. 1. Spasm of the descending colon. Observation during painful period.

colitis" (more properly "mucous colic") is well known to cause similar complaints, clinical symptoms and X-ray findings.

The neurotic constitution has or may have among many other symptoms, an "irritable colon" (Bargen); if this is associated with a certain type of "secretory" disorder, the case may resemble or be a "colica mucosa"; if however not the mucus-secretion is the predominant factor, the case can not be termed any longer colica mucosa, although the irritable colon with the "string-sign," with a similar or only slightly different clinical manifestation, may still equally be present. Consequently, the "string-sign" or the X-ray demonstration of a maximally contracted, spastic colon, is not pathognomonic in its significance: it is present in *neurotics, with or without colica mucosa.*

Still another aspect of the colospasm may deserve our fullest attention, because it is important from the practical point of view, i.e. that it may occur in the most varied morbid conditions, *also without the symptoms of any neurosis.*

In my experience—in accordance with the scattered references from the literature—similar spastic contractions over the colon may be encountered in certain cases, *without* any manifestation of a neurosis, merely as *reflex* or *secondary* concomitant symptom, at a primarily existing somatic condition in the abdominal cavity (appendicitis acuta, or chronica, cholelithiasis, peptic ulcer, carcinoma somewhere in the abdomen, etc.)

REVIEW OF LITERATURE

Concerning *spasm in the appendix*, insofar as it came to my attention in my search through the literature, there was no record of any paper dealing with, or of any X-ray film, demonstrating its existence. There are, however, occasional reports in the literature, referring to a "reversed mechanism," viz. when spasm in the alimentary canal was noted as a secondary manifestation, at a primarily existing appendicitis (Piccinino, Cristofanetti, Rendich and Ehrenpreis, Bordoni, etc.). Carman, Assmann, Meyer, Stierlin, Schlesinger, Jordan, etc., make very cursory or no references to spasms in the gastro-intestinal canal altogether, and none in the appendix.

In atrophic appendicitis the lumen is narrow, constantly, uniformly, throughout, with regular contour.

A similarly unusual feature is demonstrated by the presence of the *diverticulum-like sacculation* of the appendicular lumen.

On "prima facie" one might have diagnosed in my case a diverticulum of the appendix Such is a well established pathological entity, though rare.

True or congenital diverticulum of the appendix—an offshoot or cul de sac, often larger than the cavity of the viscus (Royster) was reported by Hedinger, Sissojeff, Jackemont, Stuerm, Gullotta, Malone, Lorrain, Martini and Rouffiac (literature see Royster, also Gullotta).

False or acquired diverticulosis has a somewhat higher incidence; two or three score cases have been observed in all (Lit.: Gullotta).

The acquired type of diverticulosis is usually classified as inflammatory or non-inflammatory. The rarer non-inflammatory type develops along the mesenteriolic attachment In the inflammatory type the diverticula may develop in any site, size or number. Ashoff's intramural abscesses frequently found in acute appendicitis, serve, regardless of their later outcome, into healing, with absorption and retraction, or perforation into a preformed peritoneal sac or into the appendiceal cavity—as a basis for a potential development of this type of acquired diverticulosis. It is generally assumed that as pre-requisite for the development of a false diverticulum, an increased intra-appendicular pressure is necessary, which in turn, is furnished as a result either of an inflammatory exudation, during an inflammation, or of a stricture, the result of past attacks, at the proximal lumen.

Cysts or cyst-like tumors of the appendix were in extremely rare cases likewise observed (Bachlechner, Oudard, Ribbert, Cameron).

The appendicular distention due to stasis (Jordan) represents a uniform, not cyst-like distention of the lumen.

COMMENT

The question to decide was, whether we are dealing here with an *anatomical diverticulum* or with the above mentioned *functional derangement?*

My reasons for assuming the functional character of this disorder seems to me to be substantiated for the following reasons: 1, the morphological picture of the appendix is dissimilar, in contrast to the anatomically fixed morphology as in the case of an organic disease; 2, other functional changes such as the spasm alongside the descending colon, co-ordinate the appendicular spasm to the colonic spasm; 3, the "experimentum crucis" is furnished by the fact, that at a time, after a physical improvement, and during a more relaxed state of mind, when no abdominal pain was complained

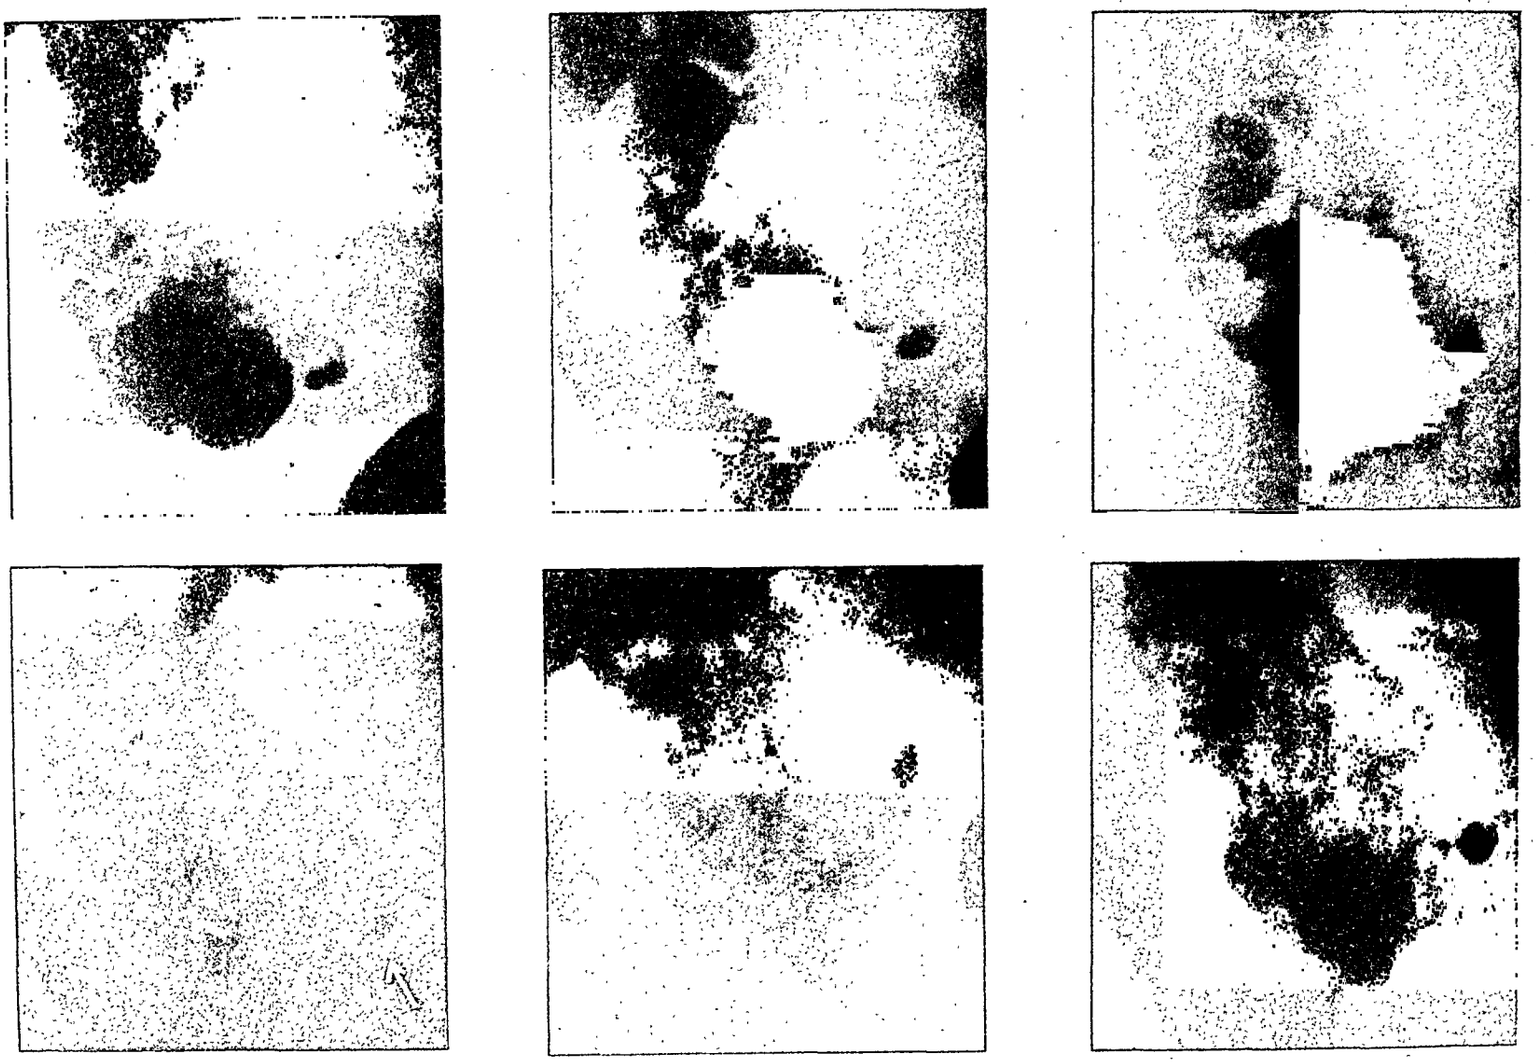

Fig. 2. Six films, taken at various intervals, 24, 31, 48 hours after barium meal, during painful period. Note size, site and location of the diverticular sacculation of the middle portion also the narrowed, spastically contracted both ends of the viscus. Spasm and sac shows shifty character to each other and to the surrounding tissues.

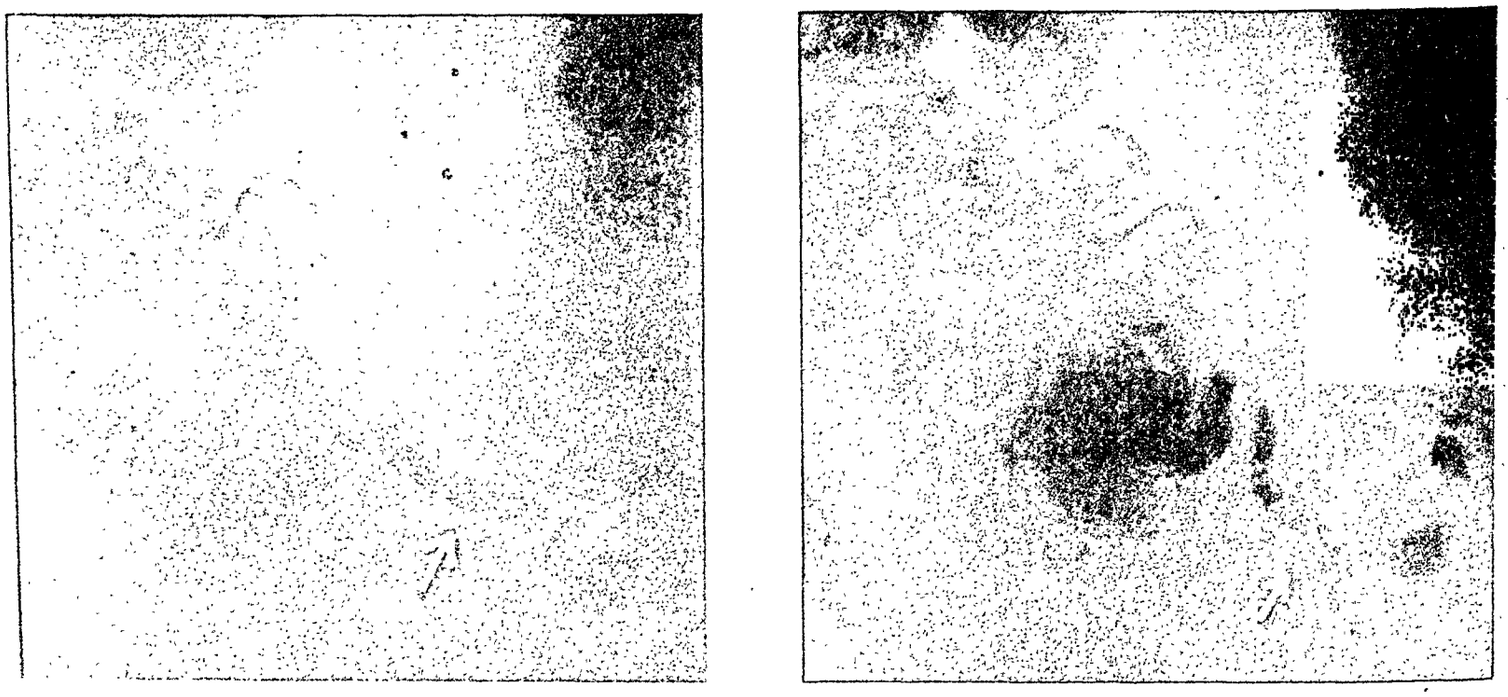

Fig. 3. Both films taken two months later, after improvement in health, in painless period. The appendix is freely movable. normal and uniform in contour, without any sign of sacculation or spasm.

of, the appendix, as demonstrated on the X-ray film, proved to be a perfectly normal appendix.

No further, or more convincing evidence could be procured by surgical or even by post-mortem inspection—both being unable to demonstrate functional changes, as roentgenological studies do.

The next question was, whether the spasm and the dilatation were merely incidentally observed together, or there might have existed some causal correlation between them.

Spasm over the colon does not produce compensatory dilatation proximally, in contrast to a narrowing, due to some organic lesion—a sign, valuable from the differential-diagnostic point of view. The shifty character and location of the spasm, furthermore the fact, that it is seldom fixed to the same site, for a longer period, may explain the failure of a compensatory hypertrophy, the first step to an organic dilatation.

Conditions in the appendix—in my case—were, however, slightly different. The partial spastic contraction squeezed the appendicular content from both ends into the relaxed middle portion. Should the proximal portion have failed to spastically contract, the appendicular content undoubtedly would have emptied into the cecum. Why just the two ends of the appendix were subjected to spasm, and not the entire length, cannot be stated. Against the assumption of any anatomical lesion, atresia, scar tissue, etc., as being responsible for this circumstance, served the fact, that at some later date, a perfectly uniform and smooth appendicular lumen was demonstrated. Against the possibility of a foreign body or a fecalith in the sac, militated the fact, that the cavity was *filled in* with the opaque material, and no external covering in form of a negative stone shadow was noted.

SUMMARY

Spasm of the descending colon co-existing with spasm of both, the proximal and the distal ends of the appendix was observed in a highly neurotic young adult.

Spasm along both ends of the appendix resulted in a diverticulum-like sacculation of the non-spastic, relaxed middle portion of the vermiform appendix, a morphological appearance hitherto often not described.

The characteristic X-ray picture as observed during the painful period, with a complete restoration to normal, in a free interval, prove conclusively, that the changes described were purely of functional origin.

SECTION V—*Therapeutics*

III. The Rate of Absorption of Salicylates and the Effect of Certain Compounds on the Rate of Absorption of Acetylsalicylic Acid from the Stomach and Intestine*

By
W. B. BRADLEY, M.D.
J. G. SCHNEDORF, M.D.
and
A. C. IVY, M.D.
CHICAGO, ILLINOIS

QUANTITATIVE determinations of the rates of gastric and intestinal absorption of salicylic acid and some of its salts are presented in this paper. In addition, the influence of certain compounds, which are used as "protectives" against the gastro-intestinal irritation caused by salicylates, on the absorption of acetylsalicylic acid has been studied.

Burow (1), Brequet (2), Houghton (3), and Delhougne (4) have reported observations on the absorption of salicylates from the stomach. These investigators, strictly speaking, did not study absorption from the stomach alone. Brequet ligated the pylorus

of the stomach in rabbits and guinea pigs and fed the drug by mouth. Delhougne produced a pylorospasm by introducing a drop of HCl into the duodenum of dogs with a chronic duodenal fistula and also fed the drug by mouth. None of these studies were quantitative; absorption was indicated by the salicyl-ferric-chloride reaction on the urine.

Pinczower (5) gave salicyl compounds orally to normal human subjects and found no differences in the rate of absorption as shown by the time of appearance in the urine. Blume and Nohara (6) determined the comparative rates of absorption of sodium salicylate upon oral and rectal administration, making quantitative analyses of both the blood and urine for salicylates at various time intervals. Following oral and rectal administration, they found traces of salicylate in the blood within 1½-2 minutes, but the concentration following rectal administration reached a higher peak in a shorter time than when given orally.

METHODS

Gastric Absorption: Anesthetized and unanesthetized dogs were used. The occluded stomach (ligature about the cardiac and pyloric orifices) of dogs under nembutal anesthesia was thoroughly washed with warm distilled water. The solutions under consideration were introduced through a glass cannula fastened by ligature in the pylorus and allowed to remain in the stomach for one hour. The residues were then washed into volumetric flasks, diluted to 500 c.c. and aliquots analyzed quantitatively for salicylates. In some cases the ureters were cannulated and diuresis established by intravenous injection of normal saline before the salicylate solution was introduced into the stomach. The urine so collected was analyzed qualitatively for salicylates with ferric chloride at five minute intervals.

In all cases 250 c.c. solutions containing 500 mg. of acetylsalicylic acid or its molecular equivalents, 383 mg. salicylic acid, 444 mg. sodium salicylate, 486 mg. calcium salicylate were used. The mixtures studied contained 500 mg. acetylsalicylic acid with either 1000 mg. sodium bicarbonate, 300 mg. calcium gluconate or 330 mg. magnesium oxide.

Gastric absorption in the unanesthetized dog was studied by one hour perfusions of 100 c.c. equi-molecular salicyl solutions through the pouch of the entire stomach (7). In some instances the urine was collected for several days

TABLE III

The effect of pH and molecular size upon the absorption of salicylates from the stomach and intestine

Drug	pH	Molecular Weight	% Gastric Abs. /hour	% Intestinal Abs. /0.5 hr.
Salicylic acid	2.5	138.05	63.9	59.4
Sodium salicylate	6.8	159.8	13.3	72.8
Calcium salicylate	6.1	350.18	47.1	58.3
Acetylsalicylic acid	2.9	180.06	48.9	17.1
Acetylsalicylic acid + Ca.-gluc.	3.5		48.3	50.7
Acetylsalicylic acid + $NaHCO_3$	7.3		27.7	14.4
Acetylsalicylic acid + MgO	9.0		19.0	17.9
Acetylsalicylic acid + HCl	1.7		58.1	
Acetylsalicylic acid + HCl	1.25		57.1	

after the perfusion and the amount of salicylate recovered determined.

Intestinal Absorption: Twenty-four inch, well-washed, but not traumatized, intestinal loops (upper ileum) of dogs under nembutal anesthesia were used. The solutions were introduced through a glass cannula and allowed to remain for 15, 30, 45, 60 and 75 minute periods. The residues were washed into volumetric flasks, diluted to 250 c.c. and analyzed for salicylates. In all cases 50 c.c. of solution containing 150 mg. acetylsalicylic acid or equivalent amounts of salicylic acid and its salts were used. The acetylsalicylic acid mixtures contained either 300 mg. sodium bicarbonate, 100 mg. calcium gluconate, or 100 mg. of magnesium oxide respectively.

Method for Determining Salicylates Quantitatively: Existing quantitative methods for salicylates were found inadequate. The method of steam distillation and subsequent ferric chloride determination of the salicylate as described by Thoburn and Hanzlik (8) was found unsatisfactory. The presence of large quantities of mucin, mucoid and other materials in the intestine which take up bromine excluded the direct application of the bromine titration method (9).

For these reasons a new method was developed. By determining the volume of carbon dioxide liberated by brominating salicylic acid in a Van Slyke apparatus, satisfactory results were obtained. Details of this method will be reported elsewhere (10).

TABLE IV

Hydrolysis of acetylsalicylic acid

Salicylate	pH of Sol.	Time	% hydrolysed
(1) Acetylsalicylic acid	1.76	2 hours	0.0+
		24 hours	0.0+

	pH Buffer Sol.		
(3) Acetylsalicylic acid	8.25 8.0	2.5 hours	0.0+
(4) Acetylsalicylic acid + Ca-gluconate	8.25 8.0	2.5 hours	0.0+

TABLE V

Dialysis of salicylates through collodion sacs

Drug	%/1.5 hours
(1) Acetylsalicylic acid	58.0
(2) Acetylsalicylic acid + Ca-gluconate	60.2
(3) Acetylsalicylic acid + $NaHCO_3$	53.1
(4) Salicylic acid	55.7

RESULTS

Gastric Absorption: The relative rates of gastric absorption of the salicyl compounds and the mixtures studied are shown in Table I. Averages of data from four dogs for each solution show the following percentage absorption in one hour; salicylic acid 63.9%, sodium salicylate 43.3%, calcium salicylate 47.1%, acetylsalicylic acid 48.7%, acetylsalicylic acid and calcium gluconate 48.3%, acetylsalicylic acid and sodium bicarbonate 25.7%, acetylsalicylic acid and magnesium oxide 19.0% (Table I).

Perfusion of the total pouch of the stomach in the unanesthetized dog for one hour showed a slightly higher rate of absorption of acetylsalicylic acid (68.6%). Of the amount absorbed 66.9% was re-

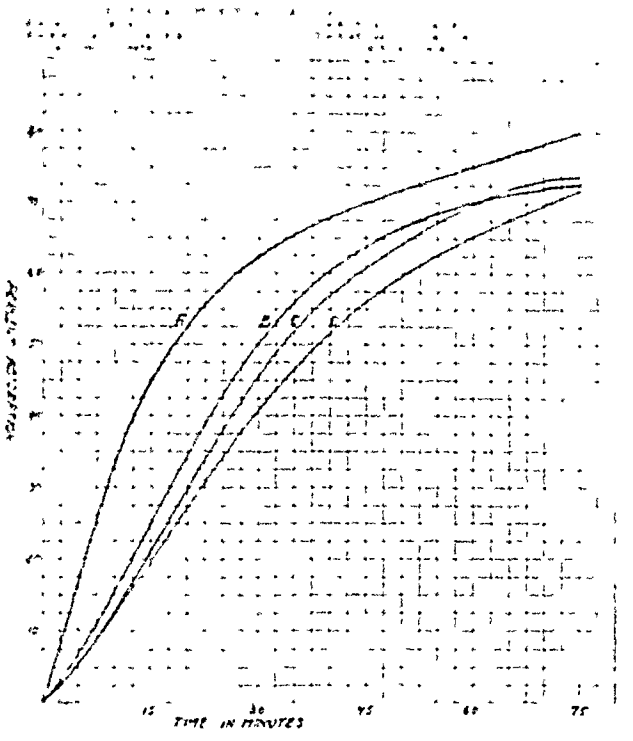

Fig. 1

covered in the urine which was collected for 48 hours (Table II).

Differences in the pH of the solutions introduced into the stomach affected the rate of absorption (Table III). Table III shows that solutions of acetylsalicylic acid and a mixture of acetylsalicylic acid and calcium gluconate which have pH's of 2.9 and 3.5 respectively are absorbed at almost the same rate (48.7% and 48.3%) whereas the solution of a mixture of acetylsalicylic acid and sodium bicarbonate (pH 7.3) is absorbed at the rate of 27.7% in one hour while only 19.0% of a mixture of acetylsalicylic acid and magnesium oxide (pH 9.09) is absorbed in the same time. When the pH of the acetylsalicylic acid solution was lowered from 2.9 to 1.7 by the addition of HCl, the absorption rate was increased from 48.9% to 58.1% per hour. At a pH of 1.25, 57.1% of acetylsalicylic acid was absorbed.

Experiments show no difference in the rates of hydrolysis of acetylsalicylic acid at these different pH's (Table IV).

No difference was found in the rate of diffusion of these various solutes through collodion sacs (Table V).

The urine gave a positive ferric-chloride test for salicylates in 10-15 minutes after the acetylsalicylic acid preparations were put into the stomach. Acetylsalicylic acid and sodium bicarbonate gave a positive test in 2 minutes while mixtures of acetylsalicylic acid and calcium gluconate or magnesium oxide gave positive tests in 15-35 minutes.

[illegible] The result of the rate of [illegible] the various [illegible] compounds [illegible] Table VI. [illegible] [illegible] 72% [illegible] acetylsalicylic acid and calcium gluconate (50.7%), acetylsalicylic acid and magnesium oxide (47.9%), acetylsalicylic acid (47.2%), and acetylsalicylic acid and sodium bicarbonate (44.4%). Curves obtained from the percentage absorption at fifteen minute intervals are presented in Figure 1.

DISCUSSION

Gastric Absorption: Quantitative recovery of only 50% of the acetylsalicylic acid introduced into the occluded stomach one hour previously, with a positive ferric-chloride test for salicylates upon the urine in 10-15 minutes leaves no doubt concerning the absorption of salicylates by the stomach. This was confirmed by perfusion of the pouch of the entire stomach in unanesthetized dogs. At the end of one hour the perfusate contained only 32% of the salicylate introduced; 68% had been absorbed. Of the amount absorbed 66% was recovered in the urine collected for 48 hours after the perfusion.

The rate of gastric absorption of these salicyl compounds appears to be dependent upon the size of the molecule and upon the pH of the solution. At similar pH's, salicyl compounds of small molecular size are absorbed at a faster rate (salicylic acid M. W. 138, 63.9% abs.) than compounds of a larger molecular weight (acetylsalicylic acid, M. W. 180, 48.9% abs.). This is demonstrated by the following equation in which molecular size and the average of the experimental data on absorption is introduced: 138:180:63.9:48.9. This is not true of the intestine.

There appears to be an optimum pH for the gastric absorption of these compounds. Greater absorption was obtained with acid pH's than with alkaline pH's (acetylsalicylic acid pH 2.9, 48.9% abs.), (acetylsalicylic acid and sodium bicarbonate pH 7.3, 27.7% abs.), (acetylsalicylic acid and magnesium oxide pH 9.09, 19.0% abs.), (acetylsalicylic acid and HCl pH 1.76, 58.1% abs.).

The rate of hydrolysis of acetylsalicylic acid has been found to be negligible at these pH's. Hydrolysis therefore does not play any part in the varying rate of absorption observed. Similar diffusion rates through collodion sacs indicate that this physical phenomenon cannot be responsible. Gastric absorption of these compounds therefore appears to be an active physiological process which is most rapid at acid pH's and which is related to molecular size.

Intestinal Absorption: Intestinal absorption of acetylsalicylic acid was not materially affected by the addition of "protective" compounds like calcium gluconate, sodium bicarbonate, and magnesium oxide. Absorption from the intestine was not so distinctly affected by the pH of the salicyl solutions, since the acetylsalicylic acid and its different mixtures were absorbed at almost the same rate. Compounds of a smaller molecular size (sodium salicylate, salicylic acid, and calcium salicylate) were absorbed at a faster rate than acetylsalicylic acid.

CONCLUSIONS

1. Salicyl compounds are readily absorbed from the stomach.

2. Gastric absorption is more rapid with the smaller salicyl molecule and at lower pH's.

3. Calcium gluconate, which does not materially [illegible] the pH of the acetylsalicylic acid solution, does not appear to affect the rate of gastric absorption.

4. Sodium bicarbonate and magnesium oxide which raise the pH of the solution inhibit the rate of gastric absorption of acetylsalicylic acid.

5. The rate of intestinal absorption of salicyl compounds is less affected by the pH of the solution than is their rate of gastric absorption.

6. Substances used to protect against gastro-intestinal irritation, such as calcium gluconate, sodium bicarbonate, and magnesium oxide, do not markedly influence the rate of intestinal absorption of acetylsalicylic acid.

7. Sodium salicylate, calcium salicylate and salicylic acid are absorbed from the intestine at a faster rate than is acetylsalicylic acid.

The Control of Gastric Acidity in Peptic Ulcer by Alkalinized Powdered Whole Milk Tablets*

By

PAUL H. WOSIKA, M.S., M.D.

CHICAGO, ILLINOIS

BLAND foods and alkalies have been used in the therapy of peptic ulcer since early in the 19th century (1, 2, 5). Sippy (14) stressed the complete neutralization of gastric acidity, and in the past 20 years the value of this regimen has been demonstrated beyond doubt (6, 13). The administration of alkalies seems, at present, to be the most direct way of neutralizing the gastric secretion, and when this procedure fails it is because the patient has not followed the minute instructions necessary. Furthermore, physicians often fail to check the effect of the prescribed alkaline powders and foods on the acidity. Recent experimental studies have pointed to the long suspected importance of acid in the production and continuation of chronic ulcers (8, 9, 10, 11, 12). Therefore, in this report the neutralization of gastric acidity in the treatment of peptic ulcer is considered not only desirable but fundamental.

While cow's milk has been the mainstay of the usual bland diet prescribed for peptic ulcer, it is not considered "the perfect food" by many authors who have found it unsafe from the bacterial standpoint (15), a frequent cause of distress (3), and productive of a tough, hard curd capable of producing spasm of the pylorus (4). However, certain modifications of sweet cow's milk minimize these objections, and it occurred to Wosika and Emery (16, 17) that a mixture of powdered whole milk combined with alkali powders in the form of tablets might be superior to the usual Sippy regimen.

A previous paper (16) evaluated the effect of the routine Sippy treatment on the control of acidity on 46 patients with duodenal ulcer. It was found that symptoms were abolished and that the free acidity was adequately controlled in slightly more than one-half of the patients. A second report (17) compared the use of a liquid mixture of powdered whole milk plus an alkali powder, with the routine Sippy procedure, and demonstrated that the former was the more effective as a neutralizing agent.

The purpose of the present study is to determine the value of tablets composed of powdered whole milk and varying amounts of alkalies on the neutralization of the gastric acidity in patients with peptic ulcer. If the use of these tablets proves as efficacious as the usual Sippy procedure, then this convenient means of neutralizing the stomach contents should prove to be a remedy worthy of inclusion in the physician's armamentarium for this disease.

METHOD AND DATA

For this study 26 cases of peptic ulcer were selected from the Medical Clinic of Northwestern University. Roentgenological evidence for ulcer was positive in all save 2 cases and the clinical history of both of these exceptions was too typical to doubt. All of the patients were men between the ages of 26 and 66 years. The average age was 44 years. Ulcer symptoms had been present from 1 to 20 years, with an average of 9 years. Three of the group had gastric ulcers, and because they had relatively high acid values as determined by a histamine gastric analysis, they were included in the series. All the men were in poor financial circumstances; the two patients who were not on relief were unemployed.

The patients reported to the clinic about once weekly in the morning, and all meals (the usual foods allowed on the fourth week Sippy regimen) were served at Passavant Memorial Hospital at 8:00 a.m., 1:00 p.m., and 6:00 p.m. Between meals they were given tablets or milk and cream as will be indicated. From 8:00 a.m. until 7:00 p.m. 6.0 c.c. specimens were aspirated every half hour and were titrated in the customary manner for free and total acid. The pH values were determined with the quinhydrone electrode. The

Submitted April 23, 1936.

various readings were averaged and the results may be seen in the following figures.

Figure 1 shows the average free and total acid (solid lines) and pH (broken line) on 23 patients who were given the fourth week regimen. Between meals they received 90 c.c. of milk and cream on the hour and on the half hour an alkaline powder (2.0 gm. sodium bicarbonate and 0.6 gm. calcium carbonate). The free acid curve may be seen to increase steadily in spite of the regular and frequent feedings until an average reading of 25 clinical units occurs. A precipitous drop

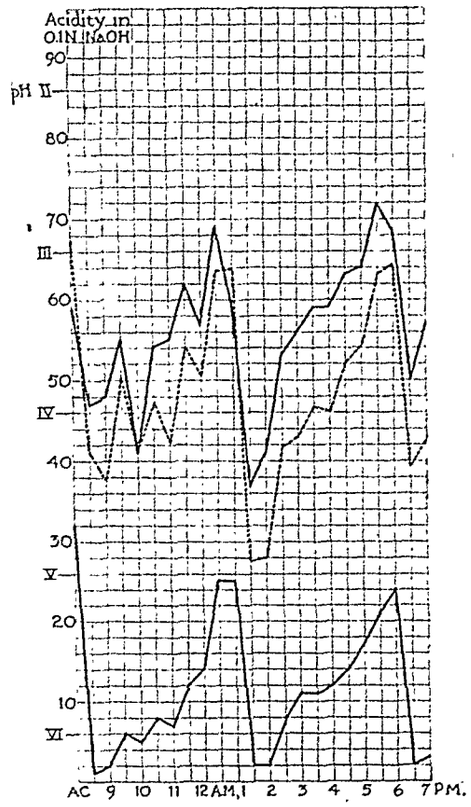

Fig. 1. Average free and total acid (solid lines) and pH (broken line) on 23 patients receiving 90 c.c. milk and cream on the hour, and 2.0 gm. sod. bicarb. and 0.6 gm. calc. carb. on the half hour.

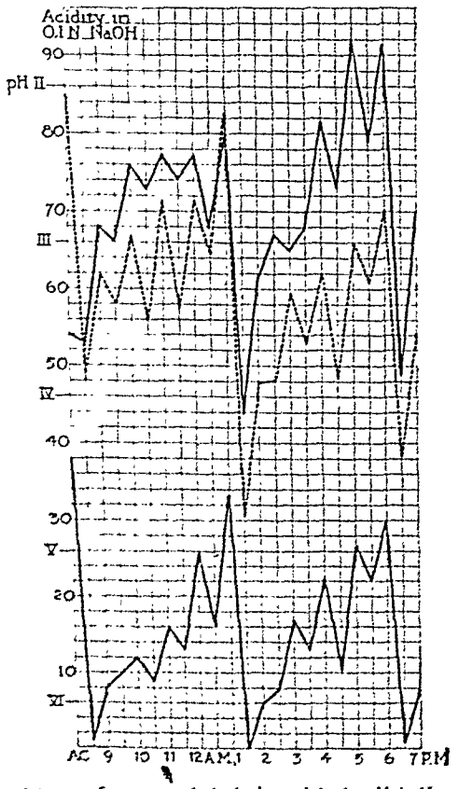

Fig. 2. Average free and total acid (solid lines) and pH (broken line) on 22 patients receiving 90 c.c. milk and cream plus a routine Sippy powder. Half hour feedings omitted.

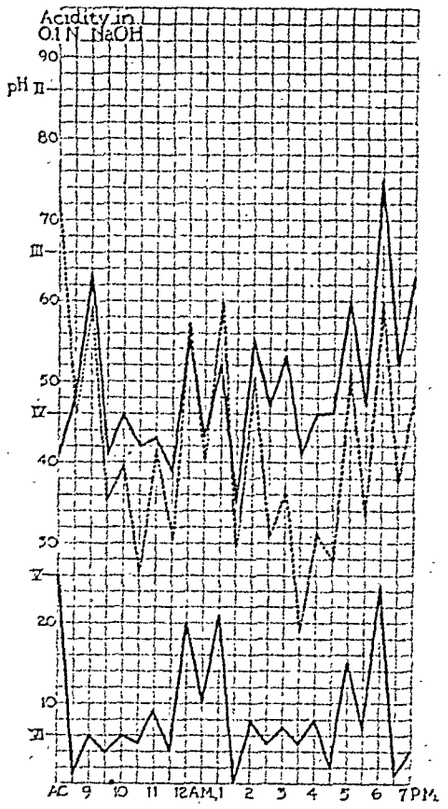

Fig. 3. Average free and total acid (solid lines) and pH (broken line) on 28 patients receiving 12.5 gm. powdered whole milk, 2.0 gm. sod. bicarb. and 0.6 gm. calc. carb. on the hour in four tablets (7115-O and O1) and nothing on the half hour.

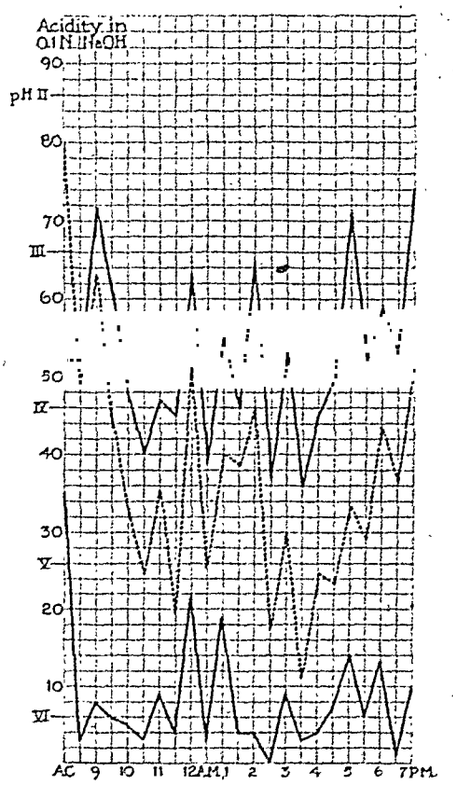

Fig. 4. Average free and total acid (solid lines) and pH (broken line) on 20 patients receiving 15.6 gm. powdered whole milk, 2.5 gm. sod. bicarb. and 0.75 gm. calc. carb. on the hour in five tablets (7115-O and O1) and nothing on the half hour.

follows dinner and similar declines may be seen after breakfast and supper. The total acid curve follows the free acid closely. The pH range for the entire day is between 3 and 5. This chart shows clearly that for these 23 male patients, the Sippy procedure, as used routinely, is inadequate for the complete neutralization of the free acid. It may also be inferred that one or two aspirations daily as is customary is insufficient for gaining an accurate picture of the acid present.

Appreciating that a smaller curd in the stomach might reduce the amount of acid, the routine powder was mixed with the milk and cream and given every

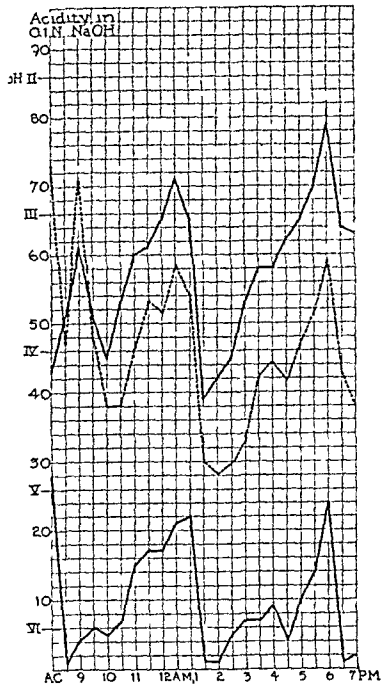

Fig. 5. Average free and total acid (solid lines) and pH (broken line) on 21 patients receiving 6.25 gm. powdered whole milk, 1.0 gm. sod. bicarb. and 0.3 gm. calc. carb. every half hour in two tablets (7115-O and O1).

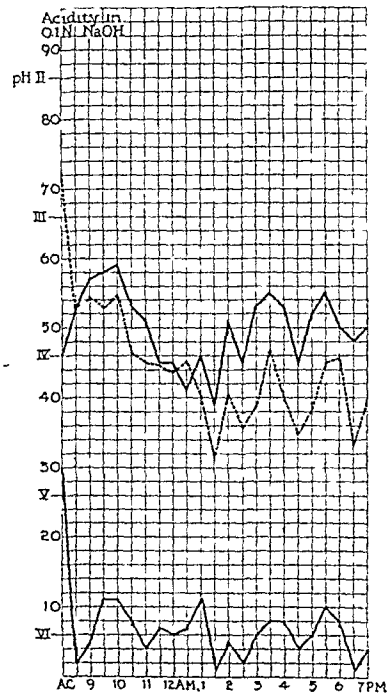

Fig. 6. Average free and total acid (solid lines) and pH (broken line) on 19 patients receiving 6.25 gm. powdered whole milk, 0.3 gm. sod. bicarb. and 1.0 gm. calc. carb. every half hour in two tablets (7115-Q or T).

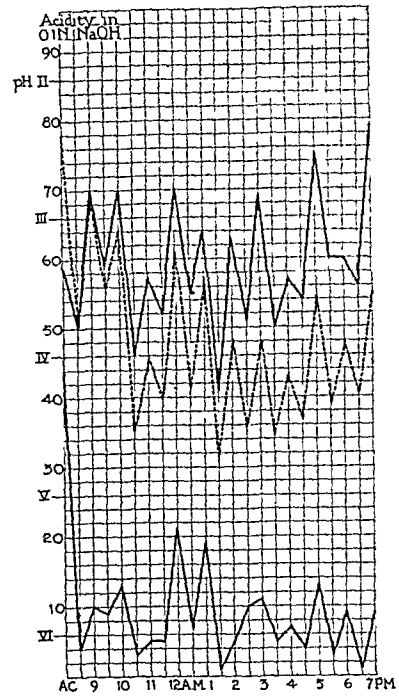

Fig. 7. Average free and total acid (solid lines) and pH (broken line) on 21 patients receiving 12.5 gm. powdered whole milk and 1.0 gm. each sod. bicarb. and calc. carb. in four tablets (7115-R or S) and nothing on the half hour.

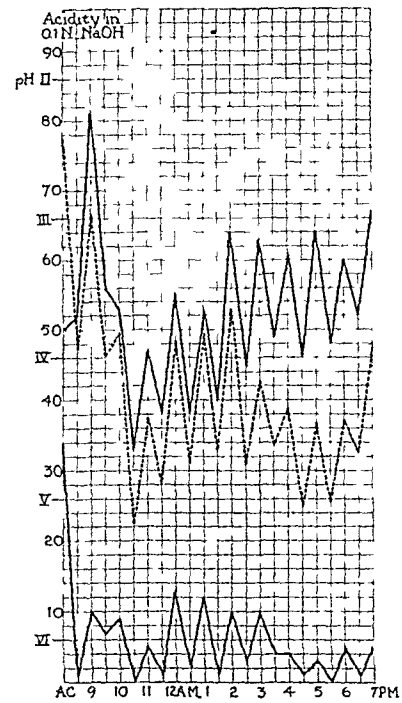

Fig. 8. Average free and total acid (solid lines) and pH (broken line) on 19 patients receiving 15.6 gm. powdered whole milk and 1.25 gm. each of sod. bicarb. and calc. carb. on the hour in five tablets (7115-R or S) and nothing on the half hour.

hour. The half hour feedings were omitted. Figure 2 depicts the average free and total acid (solid lines) and pH (broken line) on 22 patients when these hourly feedings were dispensed between the three meals. The free acid in this instance could not be considered controlled at any time except immediately following the meals. The total acid range is higher with this alkalinized powdered whole milk (Figure 2) than on the fourth week Sippy diet (Figure 1). This apparent stimulation of acid secretion is also reflected in the

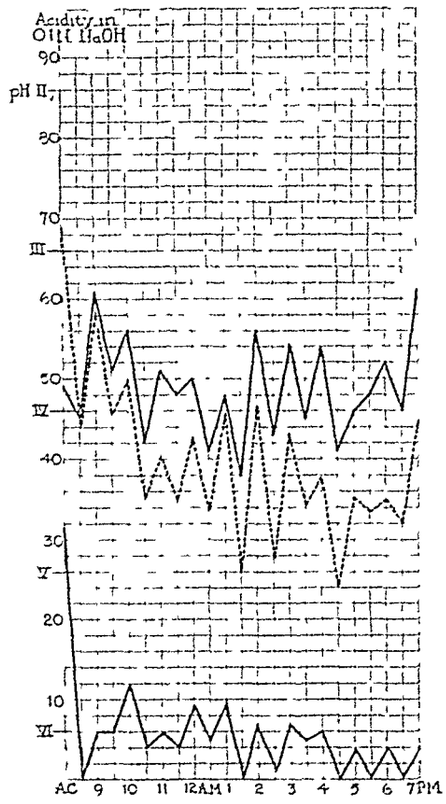

Fig. 9. Average free and total acid (solid lines) and pH (broken line) on 24 patients receiving 12.5 gm. powdered whole milk, 0.6 gm. sod. bicarb. and 2.0 gm. calc. carb. on the hour in four tablets (7115-Q or T) and nothing on the half hour.

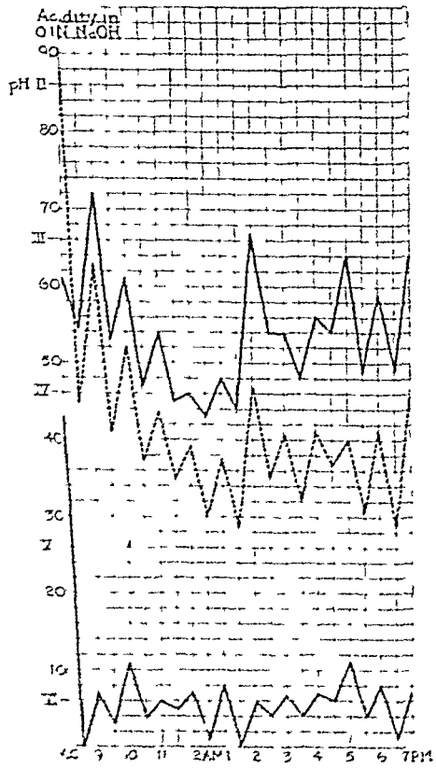

Fig. 10. Average free and total acid (solid lines) and pH (broken line) on 23 patients receiving 15.6 gm. powdered whole milk, 0.75 gm. sod. bicarb. and 2.5 calc. carb. on the hour in five tablets (7115-Q or T) and nothing on the half hour.

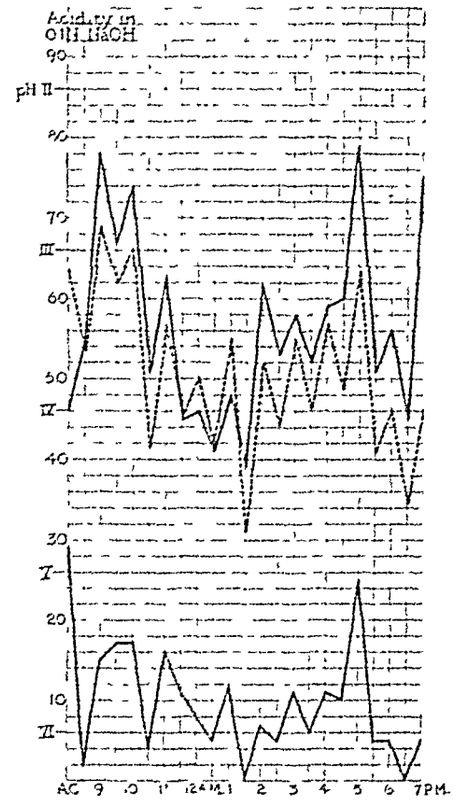

Fig. 11. Average free and total acid (solid lines) and pH (broken line) on 16 patients receiving 12.5 gm. powdered whole milk and 2.4 gm. calc. carb. on the hour in four tablets (7115-B3) and nothing on the half hour)

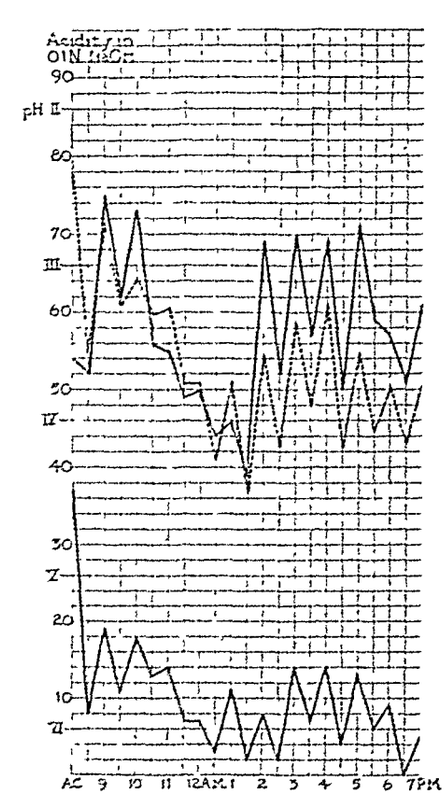

Fig. 12. Average free and total acid (solid lines) and pH (broken line) on 16 patients receiving 15.6 gm. powdered whole milk and 3.0 gm. calc. carb. on the hour in five tablets (7115-B3) and nothing on the half hour.

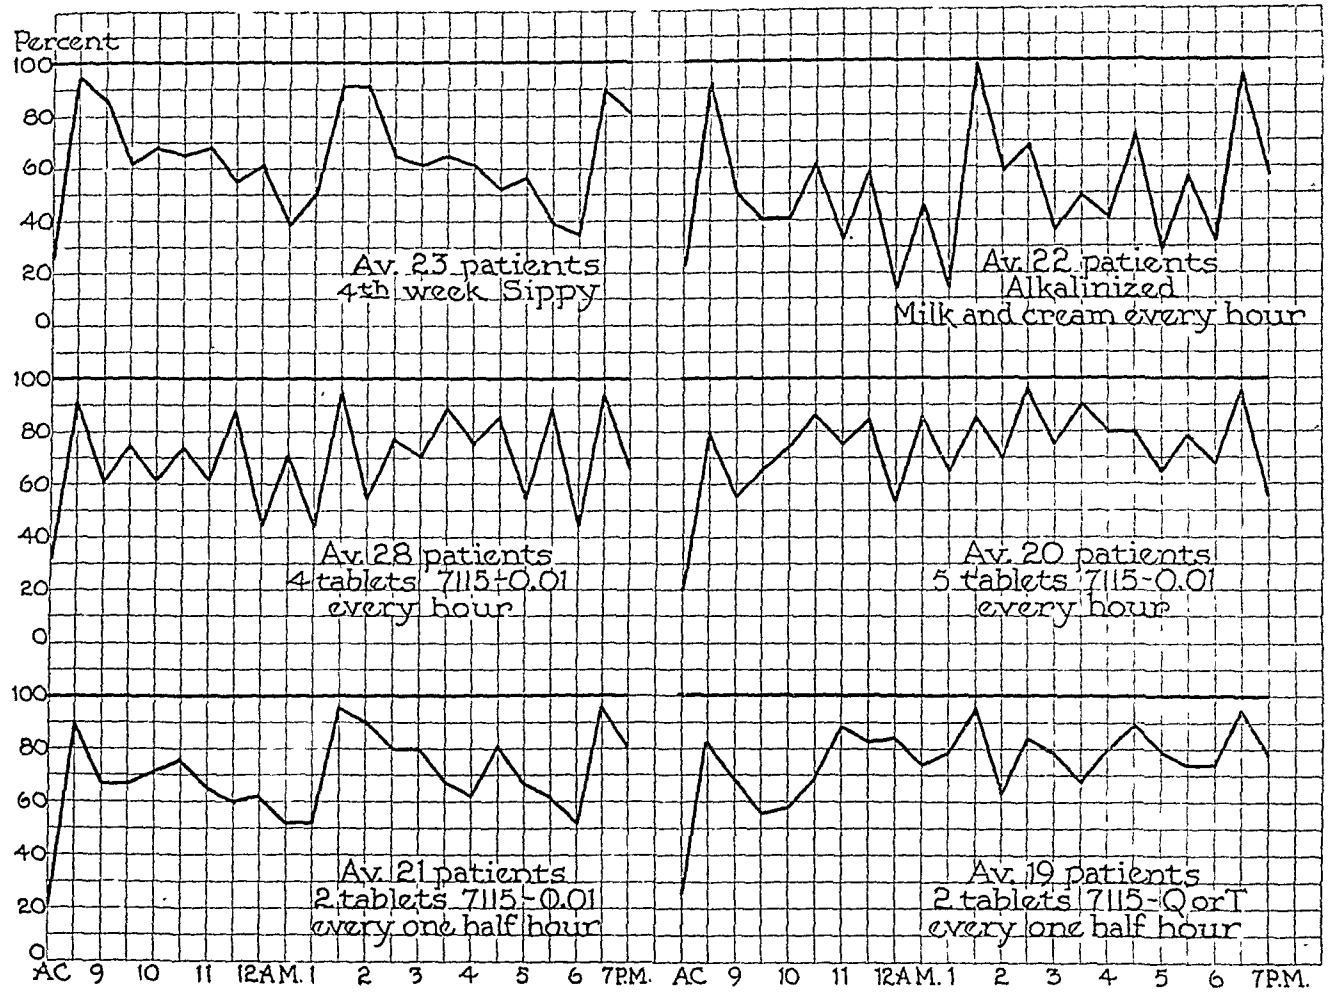

Fig. 13. Percentage of patients who revealed no free acid at each half hour analysis throughout the day.

lower pH curve. It should be remembered that exactly the same amount of food, milk and cream, and powders were used for these tests, the only difference being that the powder was mixed with the milk and the half hour feedings were omitted. If these average free and total acid values, as given on Figures 1 and 2, are averaged for the entire day, then 56 clinical units represent the total acid for the Sippy and 71 units the alkalinized milk and cream. This means that for 21 specimens collected at half hour intervals for the entire day the total acid is stimulated 15 clinical units on the latter procedure. These figures may be seen in Table I.

TABLE I

Average values of the 21 free, total and pH readings. Each line on Figures 1 to 12 is represented by one number

Procedure	pH.	F.A.	T.A.
Fourth Week Sippy	3.93	11	56
Alkalinized Milk and Cream	3.40	14	71

7115-B3—5 every 1 hour	3.68	9	58
Histamine Gastric Analysis	1.44	61	84

Figure 3 shows the average free and total acid curves of 28 patients who were given three meals, but the interval feedings were 4 tablets (7115-0 or 01), containing 12.5 gm. powdered milk, 2.0 gm. sodium bicarbonate, and 0.6 gm. calcium carbonate given every hour. Nothing was given on the half hour and only 90 c.c. of water was allowed with the tablets, equalizing the factor of dilution. The free acid curve did not rise consistently to peaks before meals. The peaks were present but were delayed in their development for 3½ hours during which time the average reading was under 10 clinical units. The inference seems logical that the simple omission of the half hour feedings is not the cause of the rise in acid values that was noted on Figure 2. Also, the total acid values were lower than on either test with milk and cream. The average total acid measurement for the day is 49. The pH readings in general follow the other curves and

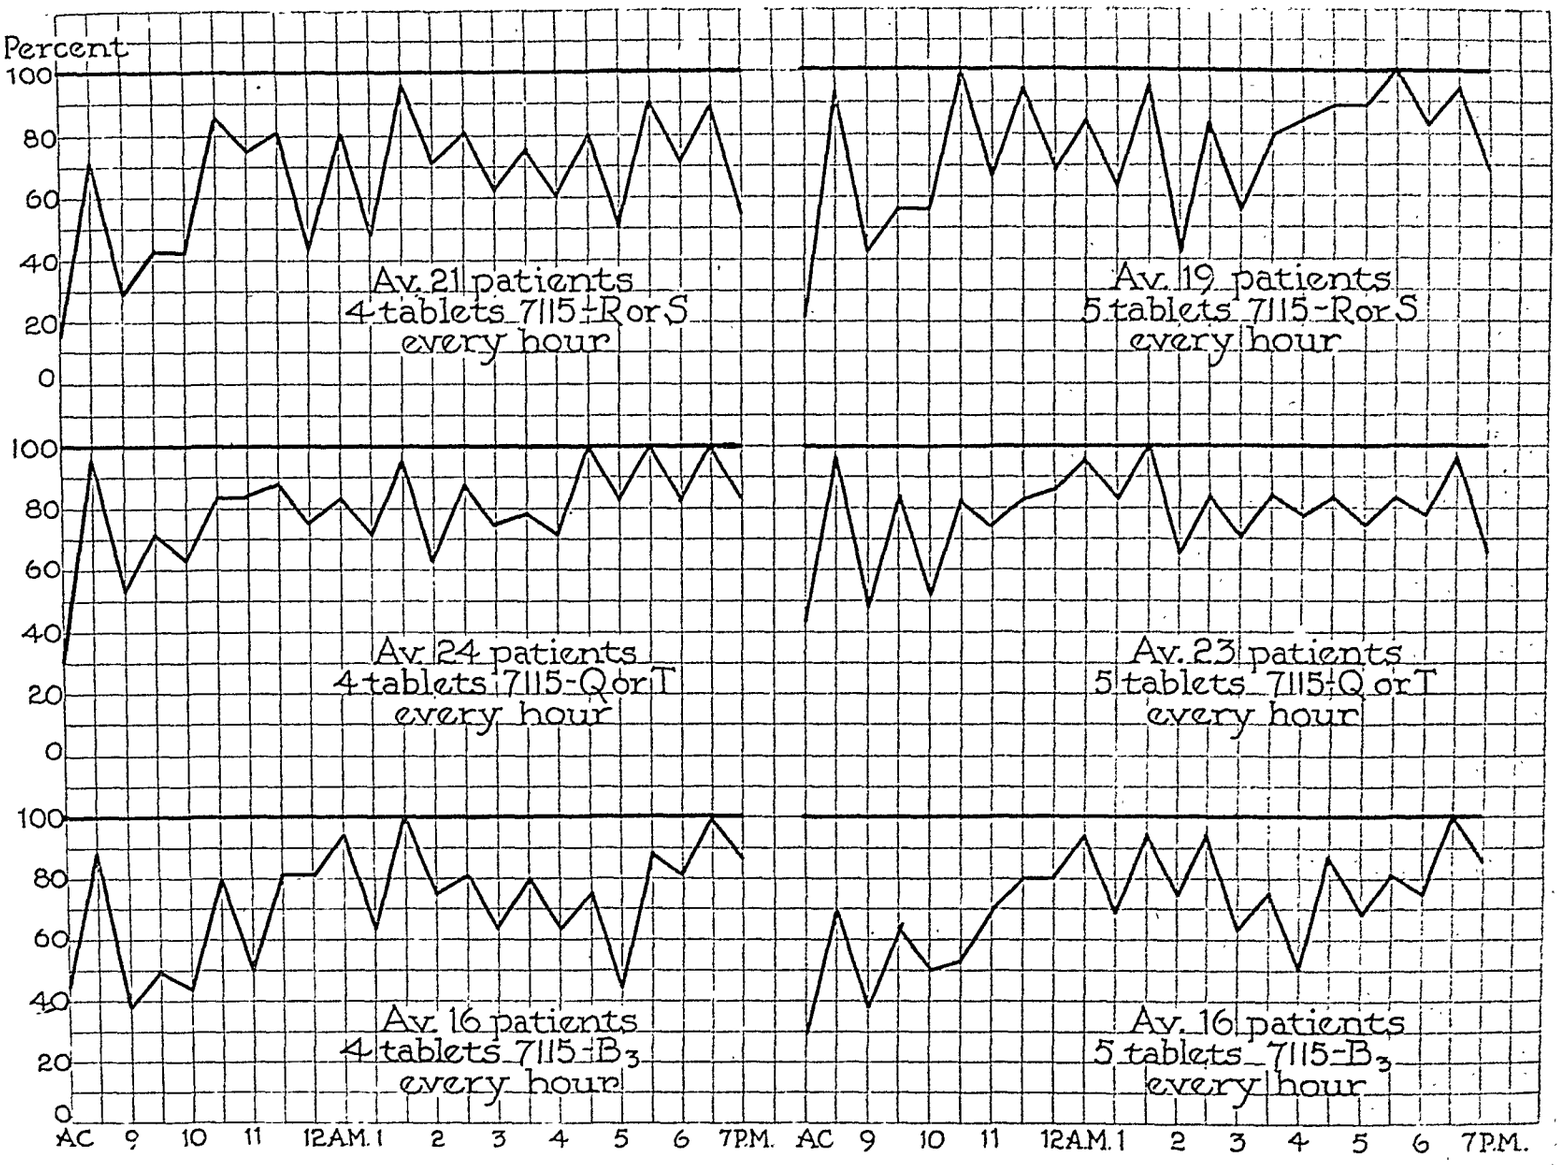

Fig. 14. Percentage of patients who revealed no free acid at each half hour analysis throughout the day.

show that lower amounts of acid were present than when milk and cream were used.

These results were not as satisfactory as had been obtained with exactly the same materials in a fluid form (17). The compressing process necessary in the manufacture of the tablets was thought to be responsible for the lowered effectiveness. Disintegration would not be so complete, making neutralization more difficult. To overcome this suspected complication, one-quarter more material was given. Thus, 5 tablets (7115-0 or 01) were administered every hour and the average results on 20 patients may be seen on Figure 4. The other factors remained the same. In this test the patients received on the hour 15.6 gm. powdered whole milk, 2.5 gm. of sodium bicarbonate, and 0.75 gm. of calcium carbonate. It becomes apparent from inspection of the chart that the mere increase in quantity will not overcome the high acid values noted. While the pH curve is lower for the day on the procedure, the results do not justify the increased amount of alkali administered.

Figure 5 shows the average free and total acid (solid lines) and pH (broken line) on 21 patients who were given 2 tablets on the hour and 2 tablets on the half hour (7115-0 or 01). The lack of acid control here is obvious. The curves suggest that the half hour feeding might be stimulating to acid secretion.

Four of the high calcium tablets (7115-Q or T) contain 12.5 gm. powdered whole milk, 0.6 gm. sodium bicarbonate, and 2.0 gm. calcium carbonate. Two of these tablets were given to 19 patients every half hour and the average free and total acid and pH is shown on Figure 6 by the usual lines. The curves do not show the wide variations noted on the previous charts. This would tend to minimize the importance of the half hour feedings in the stimulation of acid if and when the amount of sodium bicarbonate is decreased.

Another type of tablet tested contained per "dose" of 4 tablets 12.5 gm. of powdered whole milk and 1.0 gm. each of sodium bicarbonate and calcium carbonate. Figure 7 reveals the average effect of 4 of these tablets once an hour (7115-R or S) on the gastric acidity on 21 patients. This represents a reduced amount of soda from the routine tablets. The free acid curve (solid line) does not show the steadily mounting values that are apparent when tablets with larger amounts of soda are used. In general, the free acid is lower than on either of the tests when milk and cream were employed. The average values are slightly higher than when other tablets are considered (Table I). The gastric acidities of 19 patients were again studied when 5 such tablets (7115-R or S) were given every

hour. These 5 tablets contained 15.6 gm. powdered whole milk, and 1.25 gm. each of calcium carbonate and sodium bicarbonate. The average results are shown in Figure 8. The free acid averaged over 10 clinical units only on two occasions. Table I shows the average free acid to be as low as with any other material assayed. The pH and total acid compared very favorably with those noted on Figures 2 and 3.

Because the reduced amount of sodium in the tablets (7115-R or S) seemed to be an improvement to those of the routine type (7115-0 or 01), the quantity of sodium was reduced still further. This resulted in the high calcium tablets (7115-Q or T). Four of these tablets contain: 12.5 gm. powdered whole milk, 2.0 gm. calcium carbonate, and 0.6 gm. sodium bicarbonate. Figure 9 exhibits the average effect on the gastric acidity of 24 patients who were given 4 of these tablets on the hour. The free and total acid are represented by solid lines and the pH by the broken line. Wide variations of acid values are not manifested with these tablets. The free acid reading is low for the entire day and the average for the 21 analyses was 5 clinical units. The total acid was lower on the average than was found with any other procedure. The pH was higher than on tests using tablets with a larger amount of sodium bicarbonate. Twenty-three patients were studied similarly using 5 tablets (7115-Q or T); the additional tablet increasing the ingredients to 15.6 gm. powdered whole milk, 2.5 gm. calcium carbonate, and 0.75 gm. sodium bicarbonate. The average results seen on Figure 10 do not justify the increase in powdered milk and alkalies. The pH is slightly higher, the free acid averages the same, and the total acid is elevated above that reached by the 4 tablets.

The next obvious step was to attempt to control the gastric acidity with tablets made without any sodium bicarbonate. Four of these (7115-B3) were composed of 12.5 gm. powdered whole milk, and 2.4 gm. calcium carbonate, and when administered every hour, the average effectiveness on the acidity on 16 patients is shown in Figure 11. Figure 12 depicts the efficiency of 5 of these tablets (7115-B5) containing 15.6 gm. powdered whole milk, and 3.0 gm. calcium carbonate given on the hour to the same 16 patients. These tablets were inadequate for neutralizing the gastric acidity. The free acid was higher in both instances and the pH lower than when soda was used. Thus, even though sodium bicarbonate seems to stimulate acid secretion, when soda was removed from the tablets, their efficacy, as judged by the free acid control, was decreased.

Figures 13 and 14 show the percentage of patients whose acidity was absolutely zero at each half hour period throughout the day. Again, the high calcium tablets (7115-Q or T) are seen to produce a negative free acid reading in the highest number of patients in this series. This is true if 4 or 5 of these tablets are dispensed or if 2 are administered every half hour.

Table I shows the values obtained when each line on the charts were reduced to one figure. The 21 free, total acid, and pH readings have been averaged and all show a remarkable similarity. The free acid averages between 5 and 14 units. The total acid varies between 49 and 71 clinical units, while the pH varies between 3.40 and 4.55.

COMMENT

It might be well to re-emphasize the type of patient used in this series of analyses. All of the patients were male and worried about their poor financial condition. They had poor teeth or none, and adequate care for the obvious gingivitis was not possible. Certainly the conditions were not ideal for the treatment of ulcer patients when the usual admonitions are considered: Rest, freedom from worry, and elimination of foci of infections.

Ambulatory treatment was the rule and symptoms were easily controlled. Tablets were supplied for the intervals between tests at the laboratory and presumably were consumed. At best, however, treatment must be considered to have been rather haphazard when the patients were away from the clinic.

Alkalosis was not a problem. Whenever the slightest suspicion of this would arise clinically the carbon dioxide combining power of the blood was determined. No unusual values were found. Persistent headaches in one patient were relieved by the removal of several nasal polypi.

Considering the series of patients, the results were not so satisfactory as was reported earlier using a liquid mixture. However, instead of the hospitalization that had been used before, these patients were tested in a large laboratory room where many other experiments (chiefly animal) were in progress, with all their attendant odors. Therefore, while it is impossible to compare the earlier results obtained with these, the tablets of powdered whole milk are seen to be superior to the milk and cream feedings of the Sippy regimen for the neutralization of the gastric acidity.

One reason for the lower acid values when the powdered whole milk was used was because of the smaller curd produced with this material in the stomach. Observations on the curds were collected on specimens, using the Hill Curd-o-meter (7) and average values follow:

Material	Curd Tension in Grams
Milk and cream	43.0
Alkalinized milk and cream	10.4
Powdered whole milk	13.0
Alkalinized powdered whole milk	3.5
Tablets (crushed, 7115-O, routine)	5.6
Tablets (crushed, 7115-Q, high calcium)	5.4

These materials were the same in every respect with what had been administered to patients.

It is obvious from these figures that the reduced curd tension is so marked with the powdered whole milk that the beneficial effect of its use in diseased stomachs merits further consideration.

No attempt is being made to formulate a "new mode of therapy" for peptic ulcer. In this study Sippy's observations, as well as those made in the previous century on alkali therapy, are accepted as fundamental. These tablets may best be used if and when they are found to neutralize the gastric contents of the individual patient. The high calcium tablets (7115-Q or T) seem superior from the standpoint of effectiveness on the gastric acidity and taste, which latter improved markedly when the amount of soda was decreased. The

tablets are convenient and pleasant enough to take without water if necessary. Four of these may be safely recommended to patients to be taken every hour, thereby reducing by one-half the usual feedings of the routine Sippy regimen.

SUMMARY

It has been found by a study of 26 male patients with peptic ulcer that tablets composed of powdered whole milk (12.5 gm.), sodium bicarbonate (0.6 gm.), and calcium carbonate (2.0 gm.) are slightly more effective than the routine Sippy procedure as regards the neutralization of the gastric acidity.

Miss Florence Burdahl gave expert technical assistance.

The author wishes to express his appreciation for the helpful criticisms and suggestions of Drs. Charles A. Elliott, Clifford J. Barborka and Lathan A. Crandall in the preparation of this manuscript.

Annual Abstracts of Proctologic Literature

(May, 1934-May, 1935) By CLEMENT L. MARTIN, M.D., Chicago, Illinois

The complete bibliography from which these Abstracts were made will be published in full in the Transactions of the American Proctologic Society, 1935.

PRURITUS ANI

Hermance and Bacon in their contribution to Piersol's Cyclopedia of Medicine give a very concise description of the condition, the actual causes are briefly enumerated and accepted treatments given. Evaluating the treatments as they so well could have done would have helped the general practitioner but might have caused rejection of their copy in a cyclopedia.

Terrill writes as one who has cared for many cases of the disorder, he reviews the various theories and treatments and regards allergy as a factor in few cases and states "My opinion is that fully 90% of the cases that came to me are primarily of fungal origin, although many of them become secondarily infected with other organisms." He advocates constant hot dressings of mercuric bichloride 1-5000 in the acute stage and the substitution of a milder solution or a powder if drug dermatitis develops; in the subacute or chronic state, an alcoholic solution of red iodide of mercury. The incidence of trichophyton infections of the perianal skin is much less than 90% in the middle West in the Reuiewer's opinion.

The Philadelphia post-graduate group report on Gabriel's A.B.A. solution, nupercaine in oil, sterile distilled water, autogenous vaccine, and undercutting operations. We are fortunate to have such reports available. A cure has not been found. The "Resume of Experimental Studies . . . ." by Bacon should be read in full.

PHYSIOLOGY

The study of the innervation of the colon, especially the distal portion has been stimulated by the operation sympathectomy. Intradural alcohol injections are limiting and may largely replace this operation for the relief of intractable pain in the patient with inoperable pelvic cancer.

Several informative papers have appeared on colonic function. The question of glucose absorption has stimulated several investigations. *Bargen* and his associates, using the distal colonic segments in colostomized patients in their investigations, conclude that these distal segments were shown to absorb methylene blue which subsequently was excreted in the urine; atropine which caused pupillary dilatation and decreased salivation; sucrose which subsequently was excreted in the urine and in the stools from the proximal colonic segment; and glucose, which disappeared from the colonic segment, accompanied by an increased respiratory quotient or increased heat production or both. In the presence of impaired utilization of carbohydrate, increases in values for peripheral blood sugar accompanied this process.

Distal segments of the colon of man did not excrete: methylene blue, which had been orally administered in amounts sufficient to appear in the urine; glucose when 25 grams of it had been intravenously administered; sucrose, when 5 grams of it had been intravenously administered. Arsenic, when administered orally as treparsal was excreted by distal colonic segments in amounts which in some instances exceeded the urinary excretion over the same period of time.

Cutting determined by experiments in dogs that "the colon and ileum absorb dextrose from 5 and 10% solutions but they absorb less from a 10% than from a 5% solution."

Ebeling studied the absorption of dextrose solutions from colon loops in dogs and found the method satisfactory. He concludes that absorption of glucose from the colon is not adequate for clinical needs. He concludes that

hypertonic solutions (over 5%) may be harmful due to extraction of water from the tissues.

A report on *Schnohr's* "Study on the cause of death in high intestinal obstruction" reveals a study based on body fluids and body chlorides. Giving hypertonic solution of sodium chlorides prolongs life by increasing elimination of toxins by increased urine flow.

White, Rainey, et al, made observations on a patient whose cecum and terminal ileum had prolapsed through an old cecostomy wound and found among other facts that in this case the ileo-cecal sphincter was relaxed much of the time, definite antiperistalsis was not seen in the proximal colon, inhibition waves did not precede contraction waves, rythmic contractions persisted during the passage of peristaltic waves, pituitrin consistently gave some increase in the activity of the colon and diminution in tone or rythmic activity of the ileum, the ileocecal sphincter was consistently relaxed by adrenalin.

Buie and Brust have published an excellent study of 100 cases having high rectal pain. The cause of pain was not found in 19, in 26 chronic nervous exhaustion appeared to be the logical diagnosis, 12 were regarded as psychoneuroses, rectal neuralgia was diagnosed in 12, 8 had tabetic crises, 5 radium proctitis, 6 prostatic disease. Pelvic tumor, sacrococcygeal arthritis, adenomyoma of the recto-vaginal septum accounted for most of the remainder. There was one case of each of the following: neurosis, rectal neurosis, coccygodynia, cystocele and rectocele, chronic pelvic inflammatory disease. Further synopsis is impractical, the article should be read.

STRICTURE

Many of the current articles on the subject deal chiefly with lymphogranuloma inguinale.

Bacon, et al, report 24 cases of stricture of the rectum treated by Jelk's operation. They believe the operation is especially indicated in stricture due to extra-rectal infection. Postoperative dilatation for a long time is essential to maintain the size of the lumen.

Collins and Jones report a series of 422 cases of cervical carcinoma in which irradiation therapy was administered; 6 patients presented the late complication of a benign stricture of the rectum (incidence 1.4 per cent). Of the 6 cases reported 5 of the benign strictures occurred in the sigmoid colon and 1 in a lower loop of the small intestine. Because of the unusual fixation of the involved area, sigmoidoscopic examination may not reach the lesion in patients having a sigmoid lesion. Colon roentgen examination was the most important single preoperative diagnostic means of revealing stricture of the sigmoid. This rare complication was successfully treated by surgical intervention and they feel that it should not constitute a retarding influence on irradiation therapy.

SYMPTOMATOLOGY

In *Blond's* article is a viewpoint of interest, namely, that there are many cases of "nodules of the anus, fissures, and pruritus in which hyperemia or varices, either under the skin or mucosa, is not present."

SYMPATHECTOMY

See Physiology

Davis found the "presacral nerve" to be usually a plexus. He believes the main effects are on a vasomoter basis although the plexus probably has motor, glandulo-motor, and nutritional functions. He reports about 50% cures.

Behney reports 22 operations for resection of the pelvic antonomic nervous structures for pelvic pain with complete relief in 72%. Diarrhea and urinary incontinence were common the first week following operation.

Atlee reports a favorable percentage with respect to cure and partial relief of pelvic pain following pre-sacral sympathectomy.

THERAPEUTICS

Swalm states the compound of aluminum silicate (kaolin) with aluminum hydroxide in certain intestinal disorders has been shown both experimentally and chemically to possess greater efficiency than kaolin alone.

MacNeal, et al, believe that a specific bacteriologic diagnosis should generally precede the therapeutic use of bacteriophages. The preparation of bacteriophages, active against the colon bacillus, presents particular problems. The use of bacteriophage for colonic disease has not attained wide acceptance.

Warren is investigating the effects of artificial fever on hopeless tumor cases and although he has obtained no results approaching cure he obtained some encouraging effects. Combined fever therapy and deep therapy may show better results.

TUBERCULOSIS

Light therapy, diet, rest and general hygienic measures continue to be the principal treatment of intestinal tuberculosis. Those who use light therapy extensively feel that it is a valuable adjunct in their hands.

Frederick C. Smith reports on ano-rectal tuberculosis and describes the tuberculous conditions which may occur in this area.

Boles and Gershon-Cohen analyzed 1000 consecutive autopsies at Philadelphia General Hospital to determine the incidence of intestinal tuberculosis with relation to pulmonary tuberculosis. Its highest incidence was in cases of fibroulcerative cavernous pulmonary tuberculosis, "one might suspect in this group that there is no intestinal ulceration without pulmonary ulceration." It was present in only 18% of early or exudative cases. It was not observed in any case of chronic fibroid or miliary tuberculosis. Primary hyperplastic tuberculosis or tuberculoma was not seen in their series. They conclude that "a strong inferential diagnosis of the disease can be made when one considers it in its relation to the various types of pulmonary tuberculosis and as a result of evidence secured by the double contrast barium enema."

It will be noted that *J. Westermann* reports an abdominal perineal resection for tuberculosis involving the sigmoid and rectum.

VENEREAL DISEASES OF THE RECTUM

(1) Gonorrhea

Cyril V. Black working with Dr. Tucker concludes in "Gonorrheal Infection in the Female" that re-infection from the rectum has occurred in women and that it may be relatively symptomless for a long time. He discusses the use of Theelin in aqueous solution and the Elliott method of treatment for the condition. 83% of the gonorrhea cases had rectal disease, 66% had rectal gonorrhea.

Bierman and Horowitz note that re-infection of the genital tract has occurred from the rectum.

This matter is given very little consideration, or if considered has been thought to be of little consequence by gynecologists generally.

(2) Syphilis

Buie and Butsch report a case of tertiary syphilis having multiple fissures of the anus. The patient was a woman aged 50. They note that constant discomfort in this case was a significant point in the history, unlike hemorrhoids or fissure in which discomfort is apt to be of an intermittent character.

PROLAPSE

The number of operations advised for the relief of the more severe cases of rectal prolapse attest to the fact that a uniformly satisfactory procedure for third degree prolapse has not been devised as yet. The Moschovitz operation, partially obliterating the pelvic cul-de-sac or the method of anchoring the sigmoid well up to the psoas

tendon give permanent results in selected cases. I have at times wondered how a general surgeon without great experience in this particular field would solve his problem after investigating the literature; his state would probably be "confusion worse confounded."

That third degree prolapse is essentially a hernia is a well founded assumption. However, many of the operations devised on this basis, especially those which attempt to identify isolate and shorten anterior, posterior, or lateral "ligaments" of the rectum are working with inconstant or poorly defined fascial bundles. Most operations of this group are complicated procedures with uncertain results.

In the British Medical Journal of last year, several men discuss injection therapy as applied to prolapse: Morley favors it because there is no operative risk or loss of time. Findlay uses alcohol, inserting the needle through the skin just outside the anal canal rather than through the mucosa, and advances it up along each side of the rectal wall a distance of about 2½ inches. Williamson injects alcohol from the perineum and holds the rectum up toward the coccyx by a silk-worm-gut suture for about 10 days to keep it in position while adhesions are forming. Chesser uses ionization for hemorrhoids and prolapse. Smith repairs the perineum in males with prolapse, as a perinorrhapy is done in the female, to restore the normal angulation of the anus and its normal relation to the rectum. Cannon regards rectal prolapse as a type of sliding hernia and states that it requires repair of the perineal and lateral supporting structures. He believes that the lateral supports of the rectum are defective as well as the sphincters and levatores ani. He does not believe in the injection treatment. Carrasco has published a 196 page book in French on the subject.

HISTORY

Although the name of Bodenhamer crops up every now and then as one reads the literature of rectal disease, few of our generation have more than a vague notion of his character or accomplishments. *Kleiner's* sketch of his life indicates that he was forceful and aggressive but selfish and not over-burdened by a regard for medical ethics, that he was capable, a student, and that his publications helped to advance the study of proctology.

SECTION VIII—*Editorial*

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastro-enterological Association is in no way responsible for editorial expressions.

THE ALL-OR-NONE LAW AND THE PARIETAL CELLS OF THE STOMACH*

THE all-or-none law appears to have been first formulated by Bowditch, in 1871, in the following terms: "An induction shock produces a contraction or fails to do so according to its strength; if it does so at all it produces the greatest contraction that can be produced by any strength of stimulus in the condition of the muscle at that time." (Bayless, 1915). In view of the outstanding importance which this principle has assumed in the field of nerve-muscle physiology, it is not at all surprising that several attempts have been made to apply it to the glands of external secretion as well. In the case of the gastric secretions, the first suggestion on record in this direction was made by Kahn and Yaure (1924). With the acquisition of further evidence concerning the characteristics of the parietal secretion, Babkin (1931) adopted a similar view of the matter. "If the secretory cells are subject to the 'all or none law,' *i.e.*, that they produce either a maximum of secretion or none, then the greater effect of a stronger stimulus may be explained by the greater number of glanular cells involved in the secretory process. It seems probable that the parietal cells are subject to the 'all or none' law."

Neither of the above passages, however, attempts to analyze secretory action into the several component factors which underlie the all-or-none law as it is applied to nerve and muscle. The first effort in this direction was made by Liu, Yuan, and Lim (1934); in a discussion of some of their earlier work they say: ". . . the response of the oxyntic cells is 'all or none,' as they found that the HCl 'amplitude' or concentration is virtually constant and independent of the intensity of stimulation, while the HCl rate or output varies in relation to the stimulus. The conception of concentration as amplitude, and output as rate or frequency of function places secretory activity on the same physiological basis as contraction and conduction . . . . . Hollander and Cowgill (1931) have published results which support the above view." The interpretation placed upon the work of Cowgill and myself in this quotation is not in accord with my views on the subject, although the results have definitely established the fact that the millimolar concentration of HCl in the parietal secretion is constant and of such magnitude as to be practically isotonic with the tissue fluids. (Hollander, 1934, a). On the contrary, and in spite of the characteristic nature of the secretion, I believe that at the present time there exists no evidence whatever for maintaining that the parietal cells obey the all-or-none law. A similar view regarding the inapplicability of the law to salivary secretion is developed by Barcroft (1934). Since the applicability of the law to the parietal cells is coming to be accepted more and more by gastric physiologists, it seems desirable to present an analysis of the situation which may help to clarify the issues involved.

Let us first specify the several factors which are pertinent to the problem. In the case of striated muscle these are: (1) the intensity of the applied stimulus, (2) the number of muscle fibers contained in the muscle bundle being studied, and (3) the maximal response (i.e., contraction) of each fiber which is possible under given environmental conditions, (e.g., osmotic pressure and pH of the surrounding tissue fluid). According to the all-or-none law, under a given stimulus an individual muscle fiber will respond either

*From the Laboratory of Physical Chemistry, Columbia University Dental School, Medical Center, New York City.
Submitted March 9, 1936.

with this maximal contraction or not at all. A partial response of a single fiber is impossible. Therefore, the gradation in height of contraction of the entire muscle bundle, which may be observed with a variable stimulus, is due to a variation in the number of fibers which may have responded to the stimulus at any one time. A maximal contraction of an entire muscle implies a maximal functioning of all the fibers; a submaximal contraction implies a maximal functioning of only some of the fibers. This is all quite elementary—for striated muscle.

In the case of the parietal cells, however, there are four factors instead of three; namely, (1′) the intensity of stimulus which is applied to the secreting organ, and which might be measured by the amount of histamine which reaches that organ in unit time, (2′) the number of individual parietal cells, not glands, contained in the organ, (3′) the volume of parietal secretion poured out by each cell in response to the stimulus, and (4′) the composition of this acid secretion. Since this fluid contains practically nothing other than hydrochloric acid and water (Hollander, 1934, b) this last factor, the composition, may be expressed simply as the concentration of HCl in the parietal fluid. Although we are as yet unable to measure (1′) and (2′) precisely, nevertheless these two factors are entirely analogous to the corresponding ones for muscle contraction. It is in relation to (3′) and (4′) that the difficulty arises. The degree of activity of a single muscle fiber is measured by its height of contraction, (3), whereas for the parietal cell Babkin, and Lim and his associates *assume* that it is measured by the concentration of HCl in its secretion. This view is entirely erroneous, however. Since, in any given physiological situation, the concentration of HCl in the parietal fluid is fixed at an isosmotic value, this factor (4′) may be considered as a secondary, invariant characteristic of the secretion and consequently extraneous to these considerations. Instead, the energy expended by the cell in the act of secretion is determined by the amount of fluid which it pours out during that act. Were the composition variable, it also would enter into the calculation of the osmotic work—but this is not so, at least to any degree significant for our present purpose. Consequently, the degree of activity of the parietal cell must be measured by the volume of fluid which it pours out in unit time—and solely by this volume without particular regard to its acid concentration.

Thus, in order to show that the all-or-none law can be applied in this case, we must first of all establish quantitatively the nature of the relation between intensity of stimulus and volume of secretion. As yet, there isn't a single iota of evidence to indicate the nature of this relation. The rate of histamine absorption and the proportion of this substance which may be lost to other parts of the body following injection are both extremely variable. In fact, we are utterly unable to measure the amount of the stimulus which reaches the stomach, not to speak of its parietal cells, in any particular experiment. This situation makes any sort of quantitization of stimulus-intensity well nigh impossible at this time. The same situation obtains for the volume of secretion poured out per cell per unit time, that is, the number of cells which are active at any one time. In short, not only do we not have the necessary evidence to establish an all-or-none relation for the parietal cells, but we haven't even the methods by which to collect such evidence.

It may be argued that, in order to maintain the analogy with muscular contraction, the activity factor must include the acid concentration as well as the volume of secretion. Even so, it can be shown that the inclusion of concentration presents no difficulty and in no way affects the previous argument. Let us represent the degree of secretory activity by work in the special thermodynamic sense, and express it as the product of two factors, commonly designated as the capacity factor and the intensity factor. In accordance with this view, the activity of a parietal cell would then be measured by both the volume of secretion (capacity) and its HCl concentration (intensity); the product of the two equals the actual amount of acid elaborated in unit time, expressed as number of millimoles. The analogue for muscular activity would be the work of contraction, measured by the product of the load against which the muscle was pulling and the height through which it was raised. However, the analogy is not a perfect one, since both the volume and the concentration factors are determined by the secreting cell itself, whereas only the height of contraction is determined by the muscle fiber but the magnitude of the load is imposed on the system from outside it by the investigator.

Whether we choose this view of the problem or the previous one, based solely on the volume of fluid secreted, the fact still remains that as yet we have no way even of testing out the applicability of the all-or-none law to parietal secretion. Nevertheless, this problem is of importance both to the general physiologist who is interested in the fundamentals of cellular behavior, and to the scientifically minded clinician who is seeking to understand all phases of the secretory mechanism in his search for a way by which he can stop as well as start the process of acid secretion. We already know that increased stimulation does not change the concentration of HCl in the parietal secretion proper, but it is still an open question as to whether an additional stimulus increases the number of activity functioning cells or whether it induces a greater output of secretion from all of them simultaneously. This question regarding the all-or-none relation is intimately associated with other problems too: whether or not parietal activity is a continuous process; whether the parietal cell requires long or short periods of time for recovery from its secretory actively; whether the acid is formed as well as poured out under the influence of histamine, or whether it can be formed in the cell at any time and stored until its expulsion is induced by the proper stimulus. In order to make any headway with these problems, we must first of all introduce new experimental procedures, methods which are quantitatively precise and controllable. By comparison with the methods of the nerve-muscle physiologists, our own methods of study are still extremely crude, and we must emulate these investigators in regard to the mechanization of their techniques. Only by so doing can we hope to settle conclusively many of the physiological problems which

beset us in the gastro-intestinal field—among them the applicability of the all-or-none law to gastric secretion.

F. Hollander, New York City.

DISTAL OR REGIONAL ILEITIS, ULCERATIVE ENTERITIS — NOT AN ENTITY*

IN 1932, Crohn, Ginzburg and Oppenheimer (1) believed that they had separated from the benign granulomata of the intestine, a subacute or chronic, necrotizing or cicatrizing process limited to the distal ileum. It occurred in the young, was of unknown etiology, was regarded by them as a pathologic and clinical entity and designated as "distal" or "regional ileitis."

Pathologically, the process involved 20 to 30 cms. of the terminal ileum. It ended abruptly at the ileocecal valve. The early lesions rarely seen, except at operation for appendicitis which condition it simulated, were never resected in the hope of spontaneous resolution. Here the affection appeared as soggy, oedematous, hose-like. The later stages, resected and studied more closely, showed varying degrees of mucosal inflammation, with eventual hyperplastic and exudative changes in the underlying structures. The lumen usually was encroached upon, the intestine above becoming dilated. Subsequently, repair in the form of fibrosis with stenosis occurred. Finally—possibly from pressure and from further trauma—a tendency to chronic perforation and fistula formation was noted. Microscopically, the lesion was seen as a non-specific inflammation affecting in varying degrees, first, the mucosa and, subsequently, the remaining walls with eventual fibrosis and multiple fistulae formation.

The clinical features were not unlike those encountered in ulcerative colitis. Subjectively, diarrhea, not so marked as in the latter, was the outstanding symptom. Loss of weight, fever and pallor were evident depending on the extent of the process. Objectively, a palpable mass—in the subacute and chronic stages—was constantly noted; anaemia, emaciation, a post operative scar of a previous appendectomy, and evidences of fistula formation and intestinal obstruction often were noted. The stool was positive for occult blood, roentgen phenomena, described by Kantor (2), indicated a deformed ileum frequently with dilatation above and a delay in motility, and negative rectosigmoidoscopy and roentgenology of the large intestine. No evidence was obtainable of pathogenic bacteria or parasites, intestinal tuberculosis, tumors, foreign bodies, Hodgkin's disease, or actinomycosis.

The clinical course was constructed upon the pathological anatomy noted above: the *first stage* simulated acute or subacute appendicitis; the *second*, that of ulcerative enteritis, established diarrhea a prominent symptom; the *third*, the stenotic phase, resulted in partial obstruction; and the *fourth phase* was that in which the persistent fistulae were seen. The clinical course was regarded as benign in that 13 of 14 cases were reported well, following surgery. In consequence, the treatment advised was surgical.

It must be granted that the finding of fourteen consecutive cases which, without exception, presented the above described picture, justified Crohn, Ginzburg and Oppenheimer in regarding the process as a pathological and clinical entity.

Close perusal of these data indicated that the claims to *entity* were based on two observations: *first*, the presence of a granulomatous process of unknown etiology, always confined to the terminal ileal segment, involving, but not extending beyond the ileo-cecal valve when the latter was intact, and not even invading the contiguous colonic tissue in the absence of the valve as when a sidetracking ileocolostomy was performed for relief; *second*, the presence of the characteristic clinical phases which were noted above.

A year after the communication of Crohn, *et al*, Harris, Bell and Brunn (3) reported an identical process involving the jejunum as well as the ileum. At the time this was questioned by Crohn (4) since the diagnosis was a clinical one, made at operation when there may be difficulty in distinguishing ileum from jejunum. Subsequently, the latter (5) confirmed this finding and the original concept was extended to include "jejunitis." Early in 1934, Colp (6) presented an identical, synchronous process affecting ileum and cecum and shortly thereafter P. W. Brown and co-workers (7) reported five cases involving the ileum, cecum and part of the ascending colon. Phillips (8) and Röpke (9) also described this process both in ileum and cecum. These concurrent small and large intestinal inflammations were granulomatous and hyperplastic and were not to be confounded with ileitis from extension of a severe colonic process where it is "destructive and denuding as it is in the colon" (5).

With regard to its unknown etiology, in 1935, Felsen (10) stated that he had traced eleven cases of acute and eleven of chronic distal ileitides to bacillary dysentery. Crohn (5) answered that he had encountered only "one positive agglutination against dysentery organisms in ileitis . . . ." He added that he was "not unwilling to deny absolutely the possible bacillary dysentery etiology of ileitis as well as of colitis." Therefore there come into being—subject to confirmation—at least two etiologic factors in this process, one possibly known and one or more still unknown. In this connection, it is conceivable that acute small intestinal and proximal colonic processes seen in epidemic food poisonings possibly due to staphlococcic and streptococcic endotoxins might very well become chronic in an occasional instance and might result in the lesions described above. Powers (11), Homans and Hass (12) and Clute (13), believed that there was a possible, although unproved, relationship of this involvement to recent or remote appendicitis. Even as to symptoms, the rapidly accumulating literature suggests their inconstancies. Thus, Probstein and Gruenfeld (14), in reporting three cases of acute regional ileitis, state that "no uniformity of symptoms (occur-

*From the Department of Medicine, Gastro-intestinal Section, (T. R. Brown, Chief), the Johns Hopkins University and Hospital, Baltimore.
Submitted June 23, 1936.

red) which would facilitate preoperative recognition in the future."

In short, there has been described a granulomatous, hyperplastic process originally regarded as an *entity*, chiefly by virtue of its limited ileal location and unknown etiology, which has subsequently been found to involve the jejunum, cecum and ascending colon with identical pathologic and very similar but often dissimilar clinical manifestations, and which now seems to be due at least, in some instances, to *B. dysenteriae*. In consequence, it is believed that claims to *entity* cannot rightfully be maintained. On the basis of the critical analysis of the available data, it would seem that we are dealing with granulomatous, hyperplastic involvements which may be found anywhere in the intestinal tract. Its seeming relative propensity for the distal ileum may be due to stagnation at the ileo-cecal valve and the greater abundance of lymphatic tissue there than at other bowel segments, a factor favoring bacterial absorption (14).

However, these comments do not take away the credit from Crohn, Ginzburg and Oppenheimer as well as A. A. Berg, for clarifying the problem, and for making the profession more conscious of these processes.

Moses Paulson, Baltimore.

THE OELGOETZ CONCEPTION OF ALLERGY

To the Editor, American Journal of Digestive Diseases and Nutrition,

I have followed with much interest the papers published by Oelgoetz and his co-workers, concerning the etiology, diagnosis and treatment of food allergy. The view set forth by these workers, if it is correct, is one of the most important things that has happened in Medicine; but their ideas are so new and revolutionary that I wish to raise the following questions:

1. Many ideas which Oelgoetz has proposed are at variance with accepted facts of the physiology of digestion.

2. Most of the Oelgoetz concept is at variance with all known facts of allergy.

3. If pancreatic amylase is not eliminated in the urine, what is the source of amylase found there?

4. The authors stated in their initial paper that the injection of an extract of foods causes an outpouring of enzymes into the blood stream. Why do they not use stimulating substances in the treatment of food allergy? Why do they recommend an extract of whole pancreas?

5. The authors state, on the basis of data presented only by themselves, that the pancreatic enzymes when taken by mouth, pass uninjured through the stomach, and are absorbed from the duodenum into the blood stream in the active state. This observation is of tremendous practical importance, if it proves true. Has this observation been confirmed by others?

J. O. Christ, M.D., Centerburg, Ohio.

Doctor Crist's letter was sent to Dr. Oelgoetz; his reply follows:

I will answer the questions raised by Dr. Crist in the order in which they were presented.

1. It is true that some of the basic ideas propounded by us, especially the importance of the blood stream and the serum enzymes in the physiology of digestion, are at variance with accepted facts. We can only state that in view of the incontrovertible nature of the facts upon which our concept is based, previous ideas concerning the physiology of digestion must be revised.

Walzer and his associates have shown that whole proteins are regular constituents of normal serum. Walzer's work proves our contention that proteins in all stages of digestion, all the way from acid and alkali metaproteins (whole proteins which can be identified biologically) to amino-acids, are regularly absorbed from the normal gastro-intestinal tract. This indicates that digestion is commenced in the gastro-intestinal tract, but that it is continued and completed in the blood stream.

We have shown that the blood always contains the three pancreatic enzymes in a constant concentration of 0.2 by the test which we have devised, and it is these free buffer enzymes which enable the individual cells of the body to correct their environment, *i.e.*, change whole proteins which are toxic and which cannot be used as food, to non-toxic split products which can be used as food. We have pointed out that *all* proteins, *all* carbohydrates and *all* fats are enzymatically and physiologically *similar*. It is only the presence of the serum enzymes—which are heterolytic and thus hydrolyze all foods and other substances which come within their sphere of activity—which prevents *all* of us from being food allergic *all* of the time.

2. It is not true that our concept of food allergy is at variance with all known facts of allergy. That whole proteins are toxic to cells, and that whole proteins are regular constituents of normal blood are biologic facts. We believe that we have demonstrated *the mechanism* by which the whole proteins normally present in the blood stream are prevented from reaching the individual cells in a toxic form which cannot be used as food.

By means of our test for determining the pancreatic function, we have demonstrated the underlying pancreatic secretory deficiency or achylia which is the cause of food allergy. It should be remembered that etiologically, there are different kinds of allergy; our work is concerned only with allergy to foods. But because foods constitute by *far the greater number*, the most frequent, and the most intimate of our contacts,

pancreatic dysfunction explains a high percentage of all cases of allergy.

3. The source of amylase found in the urine, as well as the enzymes found in every organ, tissue, secretion and excretion of the body, with the exception of the heart and brain, is the pancreas. Every fluid of the body is permeated with the pancreatic (serum) enzymes in a constant concentration. In short, the cells of the body live in a solution of pancreatic enzymes which prevent any food from reaching the individual cells without first having passed through this enzyme "bath." All substances which come within the sphere of activity of the pancreatic enzymes are thus detoxicated and split to a form which can be used as food by the cells. When, as a result of pancreatic hypofunction or achylia, the enzymes are present in reduced concentration or are entirely absent, whole proteins in varying quantities reach the individual cells and there follows the symptom-complex known as food allergy.

4. The injection of food extracts regularly causes an outpouring of serum enzymes, but only in normal animals with normal pancreases. In food allergy we always find a *minus* pancreatic index (pancreatic hyposecretion or achylia). The use of stimulating substances in the treatment of pancreatic hypofunction or food allergy would be equivalent to whipping a tired horse already out of breath; a tired pancreas (whether as a result of primary disease or secondary to other systemic disease) needs help in the form of *preformed* enzymes to supplement the inadequate gland. The administration by mouth of an active extract of whole pancreas is the rational therapy.

5. The fact that the pancreatic enzymes pass through the stomach and reach the duodenum uninjured, has been verified by Ivy of Chicago, who reported at the last meeting of the American Gastroenterological Association that he has recovered from the duodenum, in the active state, 51% of pancreatic enzymes taken by mouth. Ivy stated that there can no longer be any doubt concerning the activity of pancreatic extract orally taken.

Anton W. Oelgoetz, M. D., Columbus, Ohio.

SECTION IX—*Book Reviews*

(This section is open to contributions from any medical reader, whether or not a member of the Editorial Council).

The Eleventh Revision of the United States Pharmacopeia and the Sixth Revision of the National Formulary.

The U. S. P. XI, prepared by the Revision Committee of the 1930 Pharmacopeial Convention and the N. F. VI, prepared by the National Formulary Committee of the American Pharmaceutical Association are now published and became official standards on June 1. These books, which are legally recognized as authoritative standards, are of the utmost importance to the physician in his prescribing and administration of drugs.

There are many changes in each which are too numerous to mention in a brief review. The new Pharmacopeia contains 58 new items while 119 items have been deleted. The additions to the Pharmacopeia indicate the importance of New and Nonofficial Remedies, published by the Council on Pharmacy and Chemistry of the American Medical Association as the majority have been previously recognized and described in that volume. Most of these additions have been wisely selected although some physicians will wonder why certain substances have been made official and others not. For example, Novosurol has been made official as Merbaphen, while Salyrgan, a generally preferred preparation, is not included. There are reasons for such discrimination (*i.e.* that monopolized substances are not admissible to the U. S. P); such facts are not generally known by physicians.

There is a number of changes in official names, in spelling, and in standards of purity, but fortunately very few in the composition and therefore dosage of the compounded preparations.

The N. F. VI has adopted the general style of the Pharmacopeia, a change which is a distinct improvement. This book contains 150 new items (of which 80 were deletions from the U. S. P. X) while 319 items were deleted. Amongst the important additions for the prescribing physician is Iso-Alcoholic-Elixir, which is an alcoholic vehicle which may be prescribed by name leaving the alcohol concentration to be adjusted appropriately by the pharmacist.

A. C. Ivy, Chicago.

OBITUARY

James Tate Mason: An Appreciation

JAMES Tate Mason came from a sturdy ancestry in the Old Dominion. His grandfather, Capt. Claiborne Rice Mason, was a self-educated man, and was a pioneer railroad contractor who constructed the greater part of the Chesapeake and Ohio, and much of the old Virginia Midland Railroad. He was one of Stonewall Jackson's engineers during the Civil War. In fact the firm of Mason, Rinehart & Co., has existed

JAMES TATE MASON
1882-1936

for more than a hundred years under various names, but always with a Mason in the firm, and at the present time as the Mason-Walsh-Atkinson-Kier Company is building the Coulee Dam in the State of Washington, the largest construction project ever undertaken by man.

Captain Mason's son, Dr. Claiborne Rice Mason, was also under Stonewall Jackson, was wounded and captured, and was kept as a prisoner of war at Elmira until the surrender at Appomatox. He was paroled and became a student at the University of Virginia, and later graduated in Medicine at the Jefferson Medical College in Philadelphia. He later married Mary Moore Woolfolk of Orange County, Virginia, a member of a prominent colonial family. From this union the only child was James Tate Mason, born May 20, 1882, at Lahore, Orange County, Virginia, where his father was a practitioner.

Young Tate Mason went to the Locustdale Military Academy when fourteen years old and was unusually well liked. He soon demonstrated remarkable athletic ability, particularly in baseball. He entered the University of Virginia Medical School in 1901 and made an enviable record as regards both athletics and popularity. He was a star on the baseball team and was beloved by his fellow students—in fact to the day of his death he was constantly in demand by former college friends. His scholarship was only average, but in spite of this he was as well liked by his professors as by his classmates. Even today at the University of Virginia his wholesome good fellowship and lovableness are a tradition.

In his medical schools days Mason served during summer months as assistant to Colonel Frazier, owner and manager of the Rockbridge Alum Springs. There were no vacations for him, as was so often the case in Virginia on account of the poverty of the early 1900's. Each summer he entertained his parents for a few weeks at the Rockbridge Alum Springs. His radiant and winning personality as a boy proved a valuable asset and made the Colonel so fond of him that when Colonel Frazier died thirty years later he made Doctor Mason heir to half of his small estate. Such devotion was Doctor Mason's good fortune all his lifetime, for no man ever made stauncher friends or more of them.

He graduated from the University of Virginia in 1905, took the Virginia State Board immediately, and then began a two-year service at the Philadelphia Polyclinic, now known as the Postgraduate School of the University of Pennsylvania. Always his rare personality made friends. After this he was Resident at the Municipal Hospital of Philadelphia for the Treatment of Contagious Diseases.

In the spring of 1907 the Pacific Coast Steamship Company built two ships at Camden, New Jersey. One of these, *The President*, was going around the Horn, and young Mason, just through with internships, applied for a place as ship's surgeon. The trip was to pay a hundred dollars and a ticket home from Seattle. On arrival in Seattle, after his first and only adventure as a mariner, he found the Northwest July at its best —a new country, a wonderful climate—and his youthful enthusiasm and lack of other plans for the future,

together with total assets of less than fifty dollars, made him seek a job. Within two weeks he found a position as local surgeon for the Pacific Coast Coal Company at Franklin and later at Black Diamond, Washington. There he spent two years, actively engaged in looking after the miners and their families. He always loved people—and these new people, with their trials and their babies, felt that the new doctor was a Godsend. They loved him. He returned to Seattle in 1909 to engage in practice, and the miners in trouble still came to him for the rest of his life. The old timers at Black Diamond loved him so much that many tearfully attended his funeral twenty-seven years later.

On taking up practice in Seattle he rapidly acquired a large but not particularly remunerative following. He worked hard, made friends everywhere, but had little income. Within a few months he welcomed the opportunity to become physician to the County Jail, as well as to the family of the Sheriff, the late Robert Hodge.

In January, 1911, he married Laura DeWolfe Whittlesey. Such new responsibilities spurred him to greater professional effort, particularly the arrival of his first-born, James Tate Mason, Jr., and later a daughter and another son.

He was elected Coroner of King County and took advantage of this opportunity to have a large autopsy experience and to start an Anatomical Club with his friends. The Anatomical Club later became the Seattle Surgical Society, now a flourishing organization. In 1914 he was made Superintendent and Surgeon of the King County Hospital, a position which he held until 1922. These eight years gave opportunity for a tremendous surgical experience. He took advantage of it with such deligence that, with visiting eastern surgical centers each few months, he became a finished surgeon. He was an original and unorthodox thinker, and made up for his lack of early schooling by phenomenal ability to observe and get the best out of what he saw and heard.

In 1917, Doctor Mason organized a partnership which later, with additions, became The Mason Clinic. In 1919 he and his associates organized and built the Virginia Mason Hospital, of which he was Chief Surgeon and President of the Hospital until his death.

Doctor Mason's ability as an organizer was abundently shown in his hospital adventure. A private hospital is always an adventure, and the vicissitudes of high finance were beautifully demonstrated. Financial backing was not to be had for such a venture. He finally sought aid from a mortgage company. The president told him, "Yes, we'll loan you the money, but you won't want it because it will cost too much." This was a terrible set-back, and Mason's face showed it. Suddenly the president said, "Tate, I'll see that you get your money, and I'll have some fun, too, if you will do exactly as I say. We will loan you the money at 8 per cent and 10 per cent commission, and you can have it right now—but of course you won't take it. Leave this office and drop in at your bank. Tell them I have promised to let you have your money. Tell the next bank you know the same story. Tomorrow see a couple of other concerns about borrowing, and, if I am a good guesser, you will get your money on reasonable terms and I will get a lot of satisfaction. The lender won't make a cent, and I'll have my joke."

It was done. Next day the money was obtained at normal interest, and the Virginia Mason Hospital was launched. A few years later Doctor Mason had the pleasure of burning the bonds in favor of a reasonable savings bank mortgage.

This new venture on so little capital was part of his life's ambition. He loved it and wanted it to prosper. Gradually more and more work arrived, and he became as busy in his own hospital as he had been at the County Hospital.

He was appointed Secretary to the Surgical Section of the American Medical Association, and after this time honors came fast. He was one of the founders of the Pacific Coast Surgical Association, a member of the Western Surgical, Southern Surgical, and American Surgical, as well as the Northwest Surgical and the Seattle Surgical Society. He was a member of the College of Surgeons, the American Medical Association, the Washington State Medical Association, and King County Medical Society. He was past president of the American Association for the Study of Goiter, 1930, and the Pacific Coast Surgical Association, 1931. At the time of his death he was consulting surgeon to the U. S. Marine Hospital, American Mail Line, Alaska Steamship Line, and the Northern Pacific Railroad. He was also President of the American Medical Association, surviving his inauguration *in absentia*, to this high office by five weeks.

A busy and active professional life, with his phenomenal ability to make and hold friends and patients, and much professional travel, began to take its toll. He was so much beloved that he was always a toast. As a story-teller he excelled, and as a speaker he had a unique style that everyone liked. Nurses adored him and brought him all their troubles—and he always had time for the ladies. He rarely spoke a cross word to anyone—in nearly twenty years' association he never had an argument with his partners. Yet at times he felt keenly any suggestion of a slight. A partner on one occasion had exploded on learning of a false accusation by a fellow practitioner and had announced that he was "going to tell that fellow what I know about him." Doctor Mason said, "Don't do it. If you ever need to use what you know about him it won't do any good if he knows that you know it"—showing the kindly politician that he was. Doctor Mason was deeply emotional inside, a fact known only to his close friends. He loved people, all people except a few, and the few usually never found out how he felt. He was kind and sympathetic and for this reason heard innumerable troubles of a non-professional nature. He usually saw a funny side to every situation, and always had a story to fit the occasion.

In 1932, he had a nervous breakdown and was out of the office for months. His blood pressure was up a little, and this disturbed him. At times he complained of extrasystoles and chest pains. He felt that he suffered with angina, though his partners could never agree with his own diagnosis. He recovered to the extent that he resumed his activities completely, though at times a little nervously depressed. He had been for years delegate from the Surgical Section to the House of Delegates of the American Medical Association, and this led to further political interest. In 1935 at Atlantic City he was made President-Elect of the Amer-

ican Medical Association. In November of that year he made a speaking tour for the Association, delivering a number of addresses before large audiences. He came home tired.

On Christmas Day, 1935, he went to pieces nervously and was admitted to his own hospital. Nervous symptoms predominated, and he went through a very trying time for a number of weeks. In March, he returned home, feeling much improved. He was struggling hard to regain his health in order to be inaugurated President of the American Medical Association.

After being home for about three weeks, on April 6th, he lunched with his partners and after lunch announced, "Boys, I believe I'm well. I am going to put in a full afternoon in the office"—and he did, admitting several patients for operation. That night lightning struck—an arterial thrombosis in the left leg—and forty-eight hours later, a left-sided paralysis (right cerebral thrombosis). Amputation of the leg followed, but there was no recovery. Five days after operation right arterial thrombosis and gangrene of the right leg—later other areas of gangrene—and suffering beyond human endurance. The last few weeks were lengthened and comforted by morphine and by wonderful nursing—and a devoted family who stayed by him constantly to the bitter end. The last weeks of his life were widely publicized. His inauguration *in absentia*, his listening by radio to the Kansas City meeting, the unanimous action of the House of Delegates to over-rule the ruling of the Judicial Council and to inaugurate a dying man as President—all are now matters of sad history, tributes by loving and grieving friends to comfort one about to die, and to help his family endure their sorrow.

Tate Mason never gave up hope of recovery or admitted the inevitable. He joked with his nurses and sent messages to his friends. Five days before his release from suffering he caused the writer, his closest associate, to make a rushing and emotional exit from the sick room. "John, I can't walk much this summer without any legs, and I love to be out of doors. Take me out a lot with you on your boat this summer."

J. M. B.

SECTION XI—*Societies, Programs and Proceedings*

AMERICAN PROCTOLOGIC SOCIETY

The American Proctologic Society held its annual meeting in Kansas City on May 11th and 12th, with an attendance of 175. The following were elected to Associate membership:

Dr. Harry W. Christianson, Minneapolis.

Dr. C. C. Hickman, Lincoln, Nebraska.

Dr. Lester P. Johnson, Ann Arbor.

Dr. Kenneth E. Smiley, Los Angeles.

Dr. Tom E. Smith, Dallas.

Dr. Victor K. Allen, Tulsa; Dr. Malcolm R. Hill, Los Angeles, and Dr. George H. Thiele, Kansas City, were elevated to Fellowship in the Society. Dr. Louis J. Krouse of Cincinnati was made a Fellow Emeritus.

The following officers were selected for 1936-37:

President: Dr. Marion C. Pruitt, Atlanta.

Vice-president: Dr. Clement J. DeBere, Chicago.

Councillors: Dr. Edward G. Martin, Detroit; Dr. Martin S. Kleckner, Allentown, Pennsylvania.

Secretary-treasurer: (re-elected) Dr. Curtice Rosser, Dallas.

The next annual meeting will be held in Atlantic City in June, 1937, with Dr. Homer I. Silvers as Chairman of Arrangements.

Curtice Rosser, M.D., Dallas, Secretary.

SECTION XII—"*The Clinic*"

Extra-Pancreatic Hypoglycemia*

By

JOHN FRANCIS BRIGGS, M.D.†

and

HARRY OERTING, M.D.‡

ST. PAUL, MINNESOTA

THE dramatic symptomology of the hypoglycemic state makes this symptom complex easy to recognize. Unfortunately, however, the symptoms alone do not disclose the underlying etiology of the attack, and it is this knowledge that is so essential in prescribing the proper treatment for the individual case. Literature is quite complete with the present knowledge of this syndrome, but it deals largely with the pancreatic origin of hypoglycemia. Recently one (1) of us emphasized the necessity of recognizing extra-pancreatic forms of hypoglycemia, and for this reason we take the liberty of reporting two fatal cases of extra pancreatic hypoglycemia.

REPORT OF CASES

1. Mr. H. S., a white male, 68 years of age, entered the Ancker Hospital on September 14, 1935. At the time of admission he complained of inability to move his legs, a feeling of generalized weakness which had persisted for three weeks, as well as a loss of thirty pounds in weight. He described his present condition as being the result of eating "rotten" hamburger in August, 1935. Shortly after this meal he developed crampy colicky pains which were limited to the epigastric region. After one week of this pain, nausea and vomiting occurred. The vomitus was foul smelling and green in color. He noticed that the eating of solid foods made the condition worse and when he limited his diet to liquids he obtained marked relief. The nausea, however, kept recurring and he noticed that his weight was less and that he had difficulty in walking because of his generalized weakness. Two days before his admission to the hospital, vomiting became persistent and he was forced to seek medical attention.

His past history and family history are irrevalent to the present discussion.

Physical examination revealed an extremely emaciated white male who appeared more like a man eighty years of age rather than his stated age of sixty-eight years. Temperature 98. Pulse 60. Head, alopecia totalis. Eyes, there was a definite arcus senilus present but the eyes were otherwise normal as regards to reflexes and fundus examination. Ears, canals were occluded with wax and the drums were not visible. Nose, negative. Mouth, the tonsils were deeply embedded in the fossae. His tongue was coated, but showed no atrophy. There was marked pyorrhea and dental caries. Many of his teeth were missing. Neck, thyroid was normal. No lymphadenopathy. Chest, examination of the chest was so handicapped by the marked emaciation that the findings were unreliable and will not be reported. Heart, tones clear. Apex beat is in the fifth interspace in the midclavicular line. Rate normal. No murmurs heard. Blood pressure was 86 over 56. Abdomen, examination revealed nothing abnormal. Hernial rings, pulsating masses could be felt in both inguinal canals. Rectum, negative. Genitalia, negative. Reflexes, negative. Extremities, negative.

Diagnostic impression on admission was (1) Probable gastro-intestinal malignancy, (2) bilateral inguinal hernia, (3) cachexia and inanition.

On September 14, 1935, at 1:30 p.m. the patient suddenly lapsed into coma. His respirations were rapid and shallow. The blood sugar taken at this time revealed 30 mg. of sugar per 100 c.c. of blood. 50 c.c. of 50% glucose were administered intravenously. After 30 c.c. had entered the vein the patient regained consciousness and appeared brighter. One hour later 1000 c.c. of 5% glucose and saline were given intravenously and the patient appeared normal. At 3:30 p.m. of the same day the patient again reverted to a comatose condition at which time the blood sugar level was 49 mg. per 100 c.c. blood. Despite heroic measures the patient did not respond and died at 4:00 p.m. on the day following admission.

Laboratory examination, sputum negative for tuberculosis. Gastric analysis, free hydrochloric acid 20 degrees; total 70. Hemoglobin 30%. Red blood count 2.9. White blood count 7,,850. Blood Chemistry, creatinine 1.8 mg. Urea nitrogen 32.2 mg. Calcium 7.5 mg. icterus index .10. Urine examination was negative. X-rays of the chest was negative. Basal metabolism, minus fifteen.

The *pre-mortem diagnosis was:* I. Hypoglycemia, secondary either to (1) pituitary disease, (2) pancreatic disease, (3) carcinomatosis. II. bilateral inguinal hernia.

Post mortem examination was done on the following morning, and in order to avoid repetition, only the essential portions of the necropsy will be reported. *Examination of the gastro-intestinal tract* revealed an ulcerated carcinoma on the lesser curvature in the region of the pylorus. The edges were round and elevated. In addition a healed peptic ulcer was found. Examination of the lungs revealed a bilateral bronchial pneumonia, as well as a bilateral hydrothorax. The liver showed marked atrophy and weighed only 800 grams. The rest of the necropsy showed nothing of note. *Microscopic examination* of the pancreas showed the organ to be normal. Repeated sections revealed no disturbance in the islands of Langerhans.

*From the Services at the Ancker Hospital, St. Paul, Minn.
†Assistant in Medicine, University of Minnesota.
‡Assistant Professor of Medicine, University of Minnesota.
Submitted February 24, 1936.

Section of the hypophysis revealed a slight degree of atrophy, but the histology was otherwise normal.

Summary: It appears obvious that the pancreas only played a secondary role in this instance of hypoglycemia. It is our belief that the marked cachexia and inanition which was secondary to the carcinoma of the stomach was sufficient to deplete the glycogen reserve in an already injured liver. The influence of liver atrophy upon the storage of glycogen is obvious, and no doubt played the greatest factor in producing this case of hypoglycemia.

2. The second case is that of an adult white male, L. F., age 27 years, who entered the hospital in December, 1934. At the time of admission to the hospital he complained of nausea, general weakness, canker sores in his mouth, headache, and pigmentation. He stated that he was perfectly well until about fifteen months ago when he was working for an uncle on a farm in Preston, Minnesota. He first noticed that the skin of his face, arms, and back of his hands became dark. He also noticed a dark band around his lower abdomen. This color change was first noticed by his uncle. He then began to lose weight rapidly. He weighed 158 pounds and within three months he lost about fifty pounds. Thanksgiving day of 1933, the patient developed nausea but did not vomit. He developed vertigo and marked general weakness. He consulted a doctor in Preston, who treated him until Easter of 1934. Patient then came back to Saint Paul and started going to the Dispensary. He was told that his blood pressure was low, and was given two pink capsules *b.i.d.* He was treated so until July, 1934, with marked improvement. The symptoms disappeared and the skin cleared up. He was told that his blood pressure was about normal. He then stopped treatment. About three days ago he developed nausea, general weakness, and canker sores in the mouth. He has had a headache for the past three days. He vomited on the day of admission and noticed a slight amount of blood in vomitus. He coughs occasionally but brings up very little sputum. His mother is confined to the Ancker Hospital because of pulmonary tuberculosis. Patient had a chest plate at the Wilder Dispensary in July, which was negative.

Past history: Past health good. Previous illness: measles, whooping cough, scarlet fever, mumps, and chicken pox. He has had no operations. Venereal disease denied.

Past history by systems: Head; continuous headache for the past three days. He has had vertigo. Eyes; no diplopia. Occasional blurring. Ears; no earaches. No discharge. Nose; no obstruction. No discharge. Mouth and Throat; occasional sore throat. Has one at the present time. Canker sores in mouth. Teeth need attention. Chest; occasional cough. No sputum. No hemoptysis. No retrosternal or precordial pain. Dyspnea with present attack. Also palpitation. No edema of ankles. Gastro-intestinal; appetite good previously. Poor with present attack. No food distress. No vomiting except as noted above. Bowels normal. Has noticed some red blood once in past few days. Genito-urinary; no dysuria. No hematuria. No frequency. No incontinence. Urinates three or four times a day, once at night. Habits; smokes almost 20 cigarettes per day. Did not drink during past six months. About a year and a half ago he drank a lot of alcohol for about three months, sometimes one quart a day. Weight; 155 pounds 1 year ago. U. 135. P. 135.

Marital history: Single.

Family history: Father, age 65, living and well. Mother, age 51, has tuberculosis. Three brothers living and well. Two sisters living and well. Aunt, mother's sister, died of tuberculosis. No other tuberculosis.

Physical examination reveals a white male, age 27 years. Fairly well developed, presenting a rather dark pigmented skin and possibly somewhat undernourished. Head; scalp negative. Eyes; pupils equal and regular. React to light and accommodation. Occular movements normal. Sclera slightly darkened. Ears and Nose; negative. Face; appears dark with dark pinhead sized melanin spots scattered over entire face. Never had these previously. Mouth and Throat; pharynx somewhat injected. Tonsils somewhat enlarged. Few small areas of pigmentation on buccal mucosa, especially on the right side. Teeth are in fair condition. Neck and Glands: thyroid not enlarged. Cervical and axillary glands not palpable. Chest and Lungs; depression in lower sternum. Expansion fair. Dullness in both apices posteriorly. Suggestion of few rales in left apex. Breath sounds are normal. Heart; not enlarged. Tones normal. No murmurs. Regular rhythm, but somewhat rapid, rate about 90 per minute. Blood pressure 82 over 56. Pulse 90. Abdomen; no masses. No tenderness. Liver and spleen not palpable. Skin darkened with several pigmented pinhead sized areas. Genitalia; negative. No abnormal pigmentation. Extremities: upper, definitely pigmented with several pinhead sized areas of pigmentation. No definite pigmentation of palms. Lower, very little pigmentation present.

Laboratory examination: Urine; appearance, amber. Reaction, acid. Specific gravity 1.020. Albumin, negative. Sugar, negative. Hyaline casts, occasional. Leucocytes, occasional. Erythrocytes, negative.

Examination of blood: Hemoglobin, 102%. Red blood count 5,680,000. White blood count 8,300. Polymorphonuclear 48% per 100 c.c. of blood. Lymphocytes 46%. Monocytes 1%. Eosinophile 4%. Basophile 1%. Creatinine 68 mgs.

X-ray examination of the chest was negative for calcification, left root.

Diagnostic impression on admission was: (1) Addison's disease; (2) possible pulmonary tuberculosis.

On December 7, 1934, the patient complained of headache and nausea. He vomited once during the a.m. His pulse and heart tones were weak. Blood pressure was 78 over 50. Patient felt weak. At 8:30 p.m. patient began to yell suddenly. He picked up a pitcher of water and threw it against the wall. He stated that three men came into his room and suddenly hit him on the head. He then took the pitcher and hit one of the men on the head. Patient seemed wild and confused and stated that everything was going wrong. He threw himself wildly around the bed. He was given three grains of luminal and he spit it out on the floor. *Blood sugar 48 mg. per 100 c.c. of blood.* He was finally given sodium luminal grains IV by hypodermic. The above symptoms can only be explained on a hypoglycemic basis. Patient became quiet. At 11:00 p.m. he again went on a rampage. He got out of bed and walked into other patient's rooms. He was then placed in bed in restraints. Patient was not oriented and seemed to think that he was in Rockford, Illinois. He had a horizontal nystagmus. He was given morphine sulphate grains 1/6 and 50 c.c. of 50% glucose were administered intravenously, after which the patient seemed to quiet down somewhat. On December 8th at 10:00 a.m. the patient seemed rational again, but complained of being very cold. His pulse was very feeble. Blood pressure was 58 over 30. Adrenalin M. ten was given every half hour, four times. At 2:00 p.m. 1000 c.c. of normal saline were administered intravenously. His blood pressure was 60 over 30. Blood sugar level at this time was 32 mgs. per 100 c.c. of blood. At 6:10 p.m. the patient expired.

Diagnosis: (1) Hypoglycemia. (2) Addison's Disease. (3) Atrophy of the adrenals.

Necropsy was performed the morning following death. The only essential finding at the necropsy was the complete atrophy of both adrenal glands to such an extent that

it was almost impossible to identify them in the surrounding tissue.

Microscopic examination of the adrenals revealed very few cells and almost complete replacement of the adrenal by fat tissue. Microscopic examination of the pancreas showed the islands of Langerhans to be normal.

Summary: The marked influence of the adrenals upon the maintenance of a normal blood sugar level is well known. The atrophy of the adrenals was unquestionably the only factor operating in this instance to produce hypoglycemia.

FINAL CONCLUSIONS

Two fatal cases of hypoglycemia are reported wherein the factors producing the disease were of extra pancreatic origin, namely cachexia and atrophy of the liver in the first, and bilateral atrophy of the adrenals in the second.

Regional Ileitis

By

F. GREGORY CONNELL, M.D.*
OSHKOSH, WISCONSIN

PATHOLOGY and abnormal function of the various divisions of the gastro-intestinal tract have been given much study, but that portion extending from the ligament of Trietz to the ileocecal valve has been comparatively neglected.

In the upper areas: Ileo mesenteric ileus, retro peritoneal herniae, diverticula, primary jejunal ulcer, benign or malignant tumors, disease or calcification of mesenteric glands have been described.

In the lower area: In the terminal ileum, proximal to the valve, disease processes frequently have been overlooked and when discussed, have been greatly confused, probably because of the adjacent appendix.

They may be divided into: (a) Inflammatory: specific or non-specific ileitis, with or without ulceration, stenoses, adhesions or adenopathies. (b) Neoplastic: benign tumors, carcinoids or malignant carninomata. (c) Congenital: Meckel's diverticulum, developmental defects, atresias, or "adhesions."

The carcinomata and the carcinoids (b) have been given recent careful study. The congenital defects (c) that may occur in the ileocecal region are well understood.

From the heterogenous group (a) of inflammatory lesions the so-called "benign non-specific granulomas," Crohn, Ginsberg and Oppenheim have isolated a clinical entity, described as "—a disease of the terminal ileum, affecting mainly young adults and characterized by a subacute or chronic necrotizing and cicatrizing inflammation of all the coats of the ileum which frequently leads to stenosis of the lumen and is often associated with fistula formation and a tumor mass in the right lower quadrant."

This was, at first, thought to occur only in the terminal ileum and was called "terminal ileitis," but with further study it was found in other locations of the small bowel and was therefore termed "regional ileitis."

The etiology is unknown. The affection occurs frequently in young males with a long history of fever, diarrhea, loss of weight and anaemia, malaise, abdominal pain and a clinical picture resembling non-specific ulcerative colitis, with later usually a mass in the right iliac fossa and intermittent intestinal obstruction.

X-ray barium meal, if carefully observed through the small bowel at frequent intervals, may give the diagnosis.

The barium enema, because of the situation of the lesion, will usually fail to reveal the pathology.

Because of the recent publications of numerous articles discussing the pathology, the unknown etiology, the clinical histories, physical and X-ray findings, differential diagnosis and treatment, they will not be repeated here.

CASE HISTORIES

Brief summaries of three such cases follow:

Case 1. R. O., Male, single, laborer.

History: For 14 years attacks of abdominal cramps, "gas," nausea, vomiting and constipation.

July 15, 1930. First hospitalization: *Operation* for "chronic appendicitis." No improvement.

A *second operation,* enterostomy, was performed.

August, 1934. The sixth admission to hospital for practically the same chain of symptoms. For the past year he had been an inmate of a sanatorium and was considered as having a tuberculous peritonitis.

September 3, 1934. Third operation: The diseased terminal ileum was removed and enteroenterostomy was performed.

November 6, 1934. The enterostomies were closed, one in midline and two in right iliac fossa.

August, 1935. Symptom free.

Case 2. A. M., Female, age 47 years, married, housewife. 5 children.

History: November 6, 1928. First hospitalization. For about a month had had diarrhea, no gross blood, no pain. Loss of weight. Previous history negative except for occasional gas after meals. Diagnosis, "Colitis." November 28, 1928. Discharged "Improved."

May 17, 1929. Second hospitalization. Continued symptoms. Diagnosis, "Ulcerative colitis." *First operation:* Ileo-ileostomy followed by second stage enterectomy of six

*Surgeon, St. Mary's and Mercy Hospital, Oshkosh Clinic.
Submitted April 9, 1936.

inches of terminal ileum. Followed by fairly satisfactory condition to June 4, 1934.

June 4, 1934. Third hospitalization. Tender mass baseball size in right iliac fossa. Nausea and vomiting, diarrhea, loss of weight.

June 6, 1934. First stage of Mikulicz's operation. Recurrence of tumor at site of anastomosis in terminal ileum.

June 13, 1934. Second stage of Mikulicz's resection.

July 24, 1934. Discharged from hospital in good condition, but with small intestinal fistula.

December, 1934. Present condition satisfactory, but has a persistent fistula.

July, 1935. Closure of fistula.

Case 8. Mrs. N. B., Female, married, age 29 years. 4 children, 2 miscarriages.

History: This case has been unclassified in my files since 1912, until the subject of "terminal ileitis" now serves as an excuse for including it with the two previous cases.

1905. First hospitalization (elsewhere). Appendectomy in 1905 for "chronic appendicitis." Five or six attacks in two years before operation. Was symptom-free for one year after operation. For the next six years attacks of intestinal obstruction three to five times a year, accompanied by pain and swelling in right iliac fossa.

June, 1912. Second hospitalization. *Operation:* Terminal ileum thickened and enclosed in fibrous sac. This parchment-like membrane was removed and ileum straightened out and omentum placed over bowel.

September, 1912. Third hospitalization. Symptoms of chronic obstruction. *Operation:* Ileo-sigmoidostomy.

October 15, 1912. Fourth hospitalization. Acute intestinal obstruction. *Operation:* Enterostomy.

June, 1913. Fifth hospitalization. Lower ileum markedly improved. Localized jejunitis, the most striking finding at operation. *Operation:* Gastro-enterostomy, excluding the thickened convoluted jejunum. Improved to November 13, 1913.

November, 1913. Sixth hospitalization. *Operation:* Resection of terminal ileum (serosa red, congested and rough, wall thickened, mucosa not ulcerated) and resection of ascending and half of transverse colon. The previous gastro-enterostomy and ileosigmoidostomy were functioning normally.

Up to 1925, Mrs. B. was quite comfortable with occasional digestive upsets after which she was lost track of.

SUMMARY

Three cases of regional ileitis are reported.

Credit for a real advance in gastro-intestinal disease —the recognition of terminal or regional enteritis— is due Drs. Crohn, Ginsburg and Oppenheim.

The cause is, as yet, unknown but with further study probably will be discovered.

The condition must be thought of in all cases of chronic diarrhea or constipation and in atypical abdominal disease.

In X-ray barium "progress" meals, more frequent examinations, at shorter intervals, and at different angles, may reveal abnormalities in the small bowel that would otherwise be overlooked.

Barium meal should always be supplemented by barium enema and *vice versa*, enema checked by "progress" meal.

Large incision and careful examination of terminal small bowel are indicated in all laparotomies for chronic abdominal symptoms, especially in cases operated upon for so-called "chronic appendicitis."

"Tumors" of the lower small bowel are not necessarily cancer or "carcinoids."

Spontaneous fistulae between abdominal or pelvic viscera may not be malignant.

Extensive resection, into the normal bowel, is usually successful.

Gastro-Intestinal Bleeding in Disease of the Liver and Biliary Tract

By

S. S. LICHTMAN, M.D.

NEW YORK, NEW YORK

HEMATEMESIS or melena, occurring in the course of liver and biliary tract disease, is usually associated with a ruptured oesophageal varix or the bleeding tendency of jaundiced subjects. Less commonly hemorrhages from the gastro-intestinal tract occur on a different basis and these instances deserve consideration. A classification of the types of gastro-intestinal bleeding associated with liver and biliary tract disease has therefore been attempted.

Bleeding from a varix, peptic ulcer or malignant disease of the biliary tract has been ruled out in the cases here reported. Our cases emphasize the fact that occult and gross bleeding in the intestinal tract may occur in acute gall bladder disease without jaundice and in damage of the liver parenchyma without a general bleeding tendency.

*From the Medical Division, Service of Dr. George Baehr, of The Mount Sinai Hospital, New York, N. Y.
Submitted February 6, 1936.

CASE REPORTS

Case No. 1. R. B. Subacute Yellow Atrophy of the Liver. Melena.

A female, aged 57 years, with a history of recurrent myalgias and arthralgias, recently developed severe pain in the left sacro-iliac region radiating to the left thigh

and leg. For four weeks she received intravenous injections of sodium iodide and intramuscular injections of Aolan, a milk preparation. She also received coal tar analgesics and one five grain tablet of cinchophen. One week before admission, seven weeks after receiving the therapy, she noted icterus, dark urine, anorexia, epigastric distress, and pale yellow stools.

Physical examination revealed an intense icterus. The liver was enlarged two fingers breadth below the costal margin. The spleen was not palpable. There was marked tenderness over both sacro-iliac regions. Bile was present in the stool and urine. X-ray examinations of the gall bladder and gastro-intestinal tract proved negative. Leucocytosis of 17 and 22,000 cells per cubic millimeter of blood was present despite clinical improvement. Tyrosine was demonstrated in the urine by the author's tyrosinase method. Biliary drainage indicated the presence of frank blood with some clots without trauma.

Chemical examination of the blood showed a prompt positive Van den Bergh reaction and bilirubinemia of 23 mg. per 100 c.c. The icterus index was 200. The bilirubinemia dropped to 16 and finally 14 mg., the icterus index to 140. The total cholesterol was 210, the ester fraction being 125 mg. per 100 c.c. The total, eventually dropped to 125, the ester fraction to traces.

Despite intravenous and oral administration of large amounts of carbohydrate the patient lapsed into coma. Hyperglycemia (350 mg.) and glycosuria (5 per cent) developed and were controlled by insulin therapy. The size of the liver decreased terminally. Edema and ascites appeared. She vomited coffee ground material and died in coma one month after admission to the hospital.

Necropsy showed the presence of a subacute yellow atrophy of the liver, subacute pancreatitis, ascites, hydrothorax and superficial erosions of the stomach. Histopathological examination of the liver revealed widespread destruction of liver tissue with a large amount of necrotic granular debris, pyknotic nuclei, and large areas of hemorrhage. Islands of liver cells adjoining the necrotic areas showed similar but less pronounced changes. These islands of relatively less severely injured cells were enveloped by bands of stroma containing plasma cells, round cells and polymorphonuclear cells, and by areas of hemorrhage and by portal spaces.

The presence of frank blood in the biliary drainage fluid prompted the diagnosis of an ulcerating malignant lesion of the papilla of Vater. The histological demonstration of pools of blood in the necrotic liver parenchyma established the possibility of this local source of bleeding in this type of case as severe parenchymal liver damage.

Case No. 2. A. G. Chronic Cholecystitis; Cholelithiasis; Choledocholithiasis; Melena; Hematemesis; Cholecystectomy; Choledochostomy.

A female, aged 40, a housewife, entered the hospital for relief from attacks of pain in the right hypochondrium, 20 years in duration. 20 years ago, an attack had been followed by transient jaundice. In the preceding 6 months, there had been increasingly severe attacks of pain in the right hypochondrium radiating to the back and shoulders and accompanied by vomiting. Two months before admission, icterus, dark urine and pruritus developed. 24 hours before admission she vomited a large amount of black fluid and had tarry stools thereafter.

Examination showed the presence of icterus and tenderness in the right upper quadrant of the abdomen. The rectal temperature was 100.4 degrees Fahrenheit. Chemical study of the blood indicated an icterus index of 22, a bilirubinemia of 0.9 mg. per 100 c.c.. The Van den Bergh reaction was delayed, direct, positive. The total cholesterol was 190 and the ester fraction decreased to 36 mg. per 100 c.c.

The intestinal bleeding prompted several diagnoses: ulcerating malignant disease of the papilla of Vater, ulcerating choledocholithiasis, and bleeding peptic ulcer. A plate of the abdomen revealed gall stones by X-ray. The Graham test failed to visualize the gall bladder. X-ray examination of the intestinal tract disclosed no abnormality.

Many gall stones were found at laparotomy. The bladder was removed and a single stone, the size of an olive pit was removed from the common bile duct together with much detritus. The papilla and the ducts were freely patent. A source for the bleeding was not uncovered. The stomach and duodenum were normal to palpation. The common duct was drained for nine days. The bleeding did not recur. The patient was observed for one year following operation.

Peptic ulcer was ruled out by X-ray and laparotomy. There was no hemorrhage in the gall bladder or bile ducts. There was no evidence of bleeding tendency before or after operation. There was no violent retching or vomiting. The vomiting was probably caused by the accumulation of blood in the stomach. The cause of bleeding in this case must be recorded as undetermined.

Case No. 3. Cholelithiasis, Chronic Cholecystitis, Acute Hemorrhagic Cholecystitis, Hematemesis.

S. S. A female, aged 64, a housewife, suffered from arthritis for 15 years. For a year prior to admission to the hospital the patient suffered attacks of pain in the right hypochondrium, radiating to the back and right shoulders accompanied by nausea, vomiting and chills, usually at midnight. The attack preceding the present illness was the severest. There was transient jaundice and acholic stools. Several weeks prior to admission the patient had a biliary colic associated with the vomiting of a small amount of dark blood.

The physical examination disclosed nothing significant. There was no icterus. Laboratory findings showed an icterus index of 10, bilirubinemia 0.3 mg. per 100 c.c. The Van den Bergh reaction was faintly delayed positive. The cholesterol content of the blood was 220 mg. per 100 c.c., the ester fraction 75 mg. The leucocytes were counted 11,100 per cubic millimeter.

An edematous hemorrhagic gall bladder containing one large walnut shaped stone was removed at operation. The patient ran a febrile course, 100 to 101 degrees Fahrenheit for 17 days following operation. She was finally discharged, relieved of her symptoms.

The gall bladder was assumed to be the source of bleeding. The history of hematemesis several weeks prior, indicated that the hemorrhagic process was probably dated then. The edematous state of the gall bladder interfered with the patency of the cystic duct preventing continued passage of blood into the bowel.

Case No. 4. Chronic Cholecystitis, Cholelithiasis, Hematemesis, Acute Pancreatitis, Transient Jaundice, Adiposity.

I. M. A female, aged 46, suffered post-prandial distention, belching and occasionally vomiting directly after meals. About eleven days before admission to the hospital she began to complain of vague generalized aches and three days later had a sudden onset of severe cramp-like periumbilical pains. She vomited some coffee ground material. The symptoms lasted for several hours. Vomiting recurred. Soreness about the navel persisted. The morning of admission she had a recurrence of pain and again vomited coffee ground material.

The physical examination indicated an extreme degree of adiposity. There was some tenderness in the periumbilical region. The icterus was slight. The blood indicated showed only a latent jaundice. The urea content of the blood was normal, the glucose elevated to 150 mg. per 100 c.c. The cholesterol was elevated to 300 mg. per 100 c.c. and the ester fraction was markedly depressed to 45 mg. In the next six days the total and ester fraction returned to normal. The blood amylase was definitely elevated to 16.4 units on admission with return to normal five and seven days after admission. Acetone was present in the urine, and disappeared on administration of fluids. The Graham test failed to visualize the gall bladder on

three repeated attempts. The barium meal indicated no abnormal findings. The patient ran a febrile course despite the cessation of vomiting and abdominal pain. This was attributed to a subsiding pancreatitis. Owing to the extreme adiposity, the favorable course of events and the reluctance of the patient to undergo immediate exploration, surgical intervention was deferred until considerable weight reduction was achieved. For six months symptoms did not recur. Thereafter the patient escaped observation. The cause of the hematemesis was not demonstrated.

Case No. 5. Acute Gangrenous Cholecystitis with Sloughing, Chronic Cholecystitis, Cholelithiasis, Pericholecystic Abscess, Thrombosis and Erosion of the Cystic Artery, Hematemesis, Post-Operative Bleeding.

T. N. A female, aged 45 years, had suffered two attacks of severe pressing epigastric pain radiating to the right hypochondrium 15 years previously with nausea and vomiting and once accompanied by dark urine and jaundice. She was in good health up to two days before admission to the hospital when she developed excruciating epigastric and hypochondriac pain radiating to the back and right shoulder, accompanied by nausea and vomiting and a constant dull ache in the right hypochondrium. The vomitus contained a large amount of blood, the urine was dark, the stools tarry. Icterus and pruritus were marked on admission. A somewhat tender mass was palpable in the right hypochondriac region. Due to the fact that the patient was a poor operative risk the operation was necessarily delayed for 18 days despite fever and chills. Then a huge abscess cavity containing gall stones was found in the region of the gall bladder. Aspiration of pus was followed by brisk bleeding. Transfusion was promptly performed. Hemorrhages again occurred on the 9th and 11th days after operation. Again transfusions were performed. Death occurred on the 12th day with hyperpyrexia. Following the operation the bilirubinemia which had been 3 mg. per 100 c.c. dropped to 0.5 mg.

Necropsy disclosed an acute gangrenous cholecystitis with sloughing, and fat necrosis of the pancreas. The cystic artery was thrombosed and eroded. An acute serosanguinous peritonitis was also present.

The hematemesis early in the history probably originated from the gangrenous gall bladder or eroded cystic artery which subsequently thrombosed. The post-operative bleeding occurred from the same eroded artery.

Case No. 6. Chronic and Acute Cholecystitis, Cholecysto-Duodenal Fistula, Gall Stone Ileus, Melena.

C. L. A female, aged 47 years, experienced digestive disturbances, gaseous eructations, epigastric distress, abdominal distention, and occasional vomiting over a period of seven years. Seven years before, she had an episode of sharp pain in the right hypochondrium radiating to her shoulders and back with nausea, vomiting, fever and definite jaundice. Tarry stools occurred with certainty at this time. Pain and vomiting lasted for a fortnight, jaundice for a month.

During the seven months preceding admission she had frequently noted tarry stools and had lost both weight and strength.

The examination exhibited diffuse abdominal distention, and fecal vomitus. An abdominal mass was not palpable. Enterotomy was performed and a gall stone removed. The distention and vomiting were promptly relieved. However, restlessness and hyperpyrexia set in wtih fatal outcome.

Necropsy demonstrated the status after ileostomy for impacted gall stone ileus. A cholecysto-duodenal fistula was present. A small shrunken gall bladder with ulcerated interior and containing a blood clot was found. The liver was ulcerated and perforated in the region of the gall bladder bed.

The early history of an acute episode with tarry stools seven years previously fixes the probable date of establishment of the cholecysto-duodenal fistula. The recent bleeding arose from the ulcerated areas in the gall bladder and liver secondary to the recent acute inflammatory flare-up.

CLASSIFICATION

Naunyn (1892) classified the types of bleeding associated with gall stones:

1. Cholemic, with hemorrhage into the gastro-intestinal tract.
2. Portal vein thrombosis complicating cholelithiasis with bleeding into the bowel.
3. Perforation of a gall stone into the lumen of the bowel or into the liver with gastro-intestinal bleeding.
4. Hemorrhage from the bile passages into the bowel.

Budinger (1925) developed a more comprehensive classification:

I. Hemorrhages, Non-Dyscrasic in Nature.
   - A. Spontaneous Bleeding from Bile Passages and Adjoining Vessels.
     1. Spontaneous massive bleeding from known blood vessel.
     2. Spontaneous massive bleeding from unknown blood vessel.
     3. Spontaneous bleeding from ulcerated areas and superficial lesions.
   - B. Hemorrhage from Neighboring Structures (including liver) with Drainage of Blood through Bile Passages.
     1. From aneurysms.
     2. From the liver.
   - C. Operative Hemorrhages.
     1. From known blood vessel.
     2. From unknown blood vessel.
     3. From liver bed or operative field.

II. Cholemic-Dyscrasic Bleeding.
   Multiple hemorrhages in various organs including gastro-intestinal tract.

The Author has modified this classification:

1. Hemorrhages of Local Origin.
   - A. Portal in Origin.
     1. Secondary to liver disease, i.e. portal hypertension. Ruptured varix.
     2. Secondary to portal vein disease, i.e. thrombosis, cavernomatous transformation.
   - B. Hepatic in Origin.
     1. Hepatic congestion and inflammation, i.e. acute and subacute liver atrophy.
     2. Traumatic.
   - C. Origin in Biliary Tract.
     1. Vascular. Rupture of aneurysm. Erosion of blood vessel by gall stone decubitus ulcer, or inflammation and ulceration of gall bladder wall. Post-operative bleeding vessel. Perforation of gall bladder into bowel, eroding vessel.
     2. Diffuse inflammatory disease of gall bladder with hemorrhage into lumen and no demonstrable bleeding vessel. Infarction and hematoma of gall bladder wall. Hemorrhagic cholecystitis.
     3. Neoplastic disease of passages with ulceration.

D. Gastro-intestinal in Origin.
   1. Ulcer complicating obstructive jaundice.
   2. Jaundice complicating peptic ulcer (Catarrhal Jaundice). Cicatricial contraction of the papilla of Vater.

II. Hemorrhages of Systemic Origin.
   Associated with hepatic insufficiency and hemorrhagic tendency. Gastro-intestinal erosions, toxic in origin.

CITATIONS FROM THE LITERATURE

I. Hemorrhage from the Gall Bladder.

A. Bleeding Source Demonstrable.

Schmidt (1893) described a patient with four massive hemorrhages in the course of five weeks, one accompanied by icterus. Despite gastric symptoms the presence of gall stones was suspected. Necropsy demonstrated a gall bladder with three areas of perforation into the duodenum each obturated by a gall stone. These were not bleeding. A false aneurysmal thrombotic mass was found between the neck of the gall bladder and the hepatic duct with pressure on the hepatic artery. The cystic duct was intact. Blood passed freely from the cystic into common hepatic duct and then into the bowel. It was difficult to determine whether a stone had ulcerated through the common duct and the artery with secondary aneurysmal formation or whether a marked cholangitis had weakened the vessel wall. Chiari's case, similarly, bled from the cystic artery. The gall bladder was involved in an inflammatory process.

Schnyder (1915) reported a case of fatal bleeding into the peritoneal cavity from a perforated gall bladder. Ulcerations had produced bleeding into the gall bladder and thrombosis of a blood vessel in its wall. Some blood had escaped into the common duct but recent bleeding into this duct had been prevented by blood clot formation and occlusion of the cystic duct. Ulceration had extended through the gall bladder wall, eroded a vessel and caused a fatal hemorrhage. No gall stones were present.

Lobstein noted a case with recovery following perforation of the gall bladder with bleeding into the gall bladder and the peritoneal cavity. The bladder and stones were removed. Gjellerup, Huguenin and Leaved have recorded similar instances.

Esau (1925) described a patient with abdominal colic followed by occult blood in the stool for 14 days. Local tenderness in the gall bladder region persisted. Peptic ulcer was diagnosed because of the bleeding, although the possibility of diseased gall bladder was also entertained. There was no icterus. No X-ray examination was made. The stomach and duodenum were found to be normal at the operation. 17 days after blood was first observed in the stool. A thickened gall bladder contained several stones. One was found in the cystic duct. The common bile duct was free. The entire inner aspect of the gall bladder wall was infarcted. The patient made a complete recovery.

Heusser's case (1925) recovered following cholecystectomy. Cystic duct occlusion prevented bleeding into the bowel. The gall bladder was filled with blood clots. its wall ulcerated and infarcted. The mucosa was completely denuded. Hemorrhage occurred by seepage and not by vessel erosion. Carnioley (1927) recorded a case of hemorrhagic cholecystitis with cystic duct occlusion and without intestinal bleeding.

Junghanns (1930) recorded a necropsy finding of decubitus gall stone ulcer eroding a vessel in the neck of the gall bladder. The cystic duct was patent. Death was caused by hemorrhage. Kehr has also referred to erosion of the portal vein and hepatic artery by common duct stone with profuse bleeding into the common duct. Naunyn recalled two cases with hematemesis caused by pyelthrombophlebitis secondary to pressure of a stone in the cystic duct.

Reports of gastro-intestinal bleeding in the course of the formation of cholecystoduodenal fistulae by passage of gall stones into the bowel are too common to enumerate in this brief account.

B. Bleeding Source Not Demonstrable.

Vysin (1923) reported a patient with attacks of colic and blood in the stools. Peptic ulcer was diagnosed. Ulcer was not demonstrable at laparotomy. The gall bladder was chronically thickened and shrunken and contained no stones. A bleeding source could not be found. Healing of an ulcer in the lapse of six weeks before operation was considered possible. Bleeding associated with gall bladder disease was apparently unfamiliar to the author.

Budinger (1925) recorded four cases. The first patient bled severely from a decubitus ulcer of the common duct. There was recent icterus. A large amount of blood was lost through the stomach and bowel. The gall bladder was full of pus, stones, and blood. The common bile duct was ulcerated by a stone, dilated and filled with pus and blood. Following cholecystectomy the symptoms vanished. The second case was diagnosed as gastric ulcer by X-ray. Symptoms suggested ulcer but accompanied by slight icterus existed for two months. The patient had vomited a large amount of blood before admission to the hospital. Following cholecystectomy, periodic bleeding took place from the wound and the bowel. The gall bladder wall was thickened, infected and its mucosa ulcerated. A stone was found in the cystic duct. Blood was present in the lumen of the gall bladder. A recent abscess was found. The gall bladder was adherent to the abdominal wall and the jejunum. No ulcers could be found in the intestinal tract. Fatal hemorrhage occurred from the hepatic artery. The source of early bleeding in this case was not demonstrated, unless it be assumed that the cystic duct occlusion occurred afterwards. The third case was also suspected of suffering from duodenal ulcer for one year. Attacks of acute pain occurred. The stools were often tarry. Lately the symptoms of gall bladder inflammation came to the foreground. Fever, tarry stools and jaundice developed. The X-ray indicated the presence of periduodenal adhesions. An abscess was found under the liver border. The gall bladder was filled with pus and blood, its mucosa gangrenous. The cystic duct though involved, was patent. Stones were not present. The main ducts were not involved and contained clean bile. Recovery followed cholecystectomy. In a fourth case, with gall stones and two bouts of jaundice, the patient again developed icterus. A thickened distended gall bladder containing about 100 tiny stones and blood was found at operation. A small stone occluded the cystic duct. A bleeding source was not demonstrable. Blood was not demonstrable in the stool after operation. If the cystic duct occlusion is relieved, blood in the gall bladder may reach the intestinal tract sub-

sequently. This event appears then not to be related to any immediate clinical episode.

Frick and Irland (1923) noted a case with profuse hematemesis and tarry stools at the ages of 18, 20 and 36 and slight jaundice several times. At operation a distended gall bladder containing one large mulberry stone was removed. A bleeding source was not demonstrable. X-ray examination of the bowel had been negative. The stomach and duodenum was also explored at laparotomy.

DeCourcy (1928) described three cases in this category. They suffered from gall stones. They suffered severe hematemesis one to five months before laparotomy. One had three attacks of severe hematemesis in the two years prior to operation. In two cases the stomach was incised and searched for ulcer. The gall bladders were removed in the three cases. Bleeding never recurred thereafter. DeCourcy attributed the bleeding to marked hepatitis.

Polichetti (1930) described a patient with a history of a profuse hematemesis five months previously and continuous indigestion despite ulcer therapy. A bladder containing 82 gall stones was removed. The stomach and duodenum were normal. Bleeding did not recur. Chronic intermittent intestinal bleeding was cured in a second patient with identical findings in the gall bladder. The stomach and bowel also showed no source of bleeding. Bleeding did not recur following operation.

White and Jankelson (1931) recounted six cases. The first patient had suffered three intestinal hemorrhages with gross blood in the stools in three years. Barium meals on three occasions revealed a slight irregularity on the lesser curvature side of the duodenum. This was interpreted as due to active or healed ulcer, adhesions, or gall bladder pressure. A thorough exploration was made of the interior of the stomach. No adhesions were present. The small intestine and colon were normal. A slightly inflamed gall bladder containing several stones was removed. There was no recurrence of bleeding for five years after operation, the period of observation. A second case with symptoms typical of gall stones developed hematemesis and melena. Barium meal two months later, indicated no ulcer. Gall stones were demonstrable by X-ray. Operation was not performed. A third patient gave a history of recurrent slight jaundice over a period of ten years. The present attack of colic lasted 24 hours. The patient then vomited blood and coffee ground material. Jaundice set in and the pain subsided. A pathological gall bladder without stones was removed. Jaundice recurred after freedom from symptoms for three years. A barium meal revealed no abnormality. A fourth patient developed colic and hematemesis following a cholecystostomy two years previously. A stone was now found in the cystic duct. No lesions were demonstrable in the stomach or duodenum. Bleeding did not recur following cholecystectomy over an observed period of five and one-half years. A fifth patient with a long standing history of gall stones developed a profuse hematemesis, tarry stools, and mild icterus. The patient died cholemic. There was no necropsy. A sixth subject with long standing symptoms of gall stones also developed hematemesis. A week later barium meal and X-ray of the gall bladder proved negative. Two stones were found in the gall bladder which was removed. The ducts were explored with negative findings.

Bleeding from Known Blood Vessel Without Gall Bladder Disease.

A. Aneurysm of the hepatic artery.

Aneurysm of the hepatic artery has been noted by Stokes, Lebert, Quincke, Borchers, Chiari. Schmidt (1893) reported a case associated with gall stones. Trauma or infection were incriminated. Kading (1919) reviewed the matter, referred to a case, and presented a case report. Hematemesis occurred in both cases. Duodenal ulcer was suspected but not found at operation in one case. It was considered a late result of some previous trauma. In the second case, the liver was injured by a wound and hemothorax was present. In both instances the aneurysm had ruptured into the bile passages. Kading reviewed four intrahepatic and 42 extrahepatic aneurysms of the hepatic artery. Perforation occurred into the gall bladder three times, into the cystic duct three times and into the common bile duct once. Friedman (1921) reported a case from this hospital, with jaundice, and melena seven years following cholecystectomy. Carcinoma of the hepatic ducts was suspected at laparotomy. At necropsy the source of bleeding was found to be an aneurysm of the hepatic artery which had ruptured into the biliary passages.

B. Erosion of the Cystic Artery.

Jaffée reported a fatal hemorrhage from cystic artery erosion by a peptic ulcer adherent to the liver and the lower edge of the liver. Bleeding following operations for gangrenous gall bladder are often caused by erosion of the cystic artery.

Bleeding from the Liver Parenchyma Into Bile Passages.

Quincke has referred to hemorrhage from the liver secondary to infarction and embolization. Rolleston described a case of acute yellow atrophy with intestinal bleeding the predominant symptom from the outset. Strauss (1929) reported a patient with traumatic subphrenic hematoma bleeding into the bile passages as well as intraperitoneally. Roessle demonstrated a fistulous tract from the hematoma into the bile passages postmortem.

Chronic Portal Vein Disease.

Fleischhauer (1932) and Scheidegger (1933) have recently reviewed the literature on cavernomatous transformation of the portal vein. Klempeper (1928) has reported a case in the American literature.

Occult Bleeding.

Eusterman (1913) reported occult blood in the stools of 20 per cent of patients with chronic gall bladder disease and in the gastric analyses of 43 per cent. Kehr maintained that occult blood occurred more often in the stools of patients with cholecystoduodenal fistula. Peiper (1921) found occult blood in the stool of 2 of 10 cases of cholecystitis. Wohlgemuth (1928) reported a patient with gall stones and hematomas of the gall bladder wall and occult blood in the stool. The blood disappeared following removal of the gall bladder. Statistics on the incidence of occult blood in the stool of patients with gall bladder disease are not complete since most cases are admitted to surgical wards

directly and are promptly operated upon without adequate routine study.

ETIOLOGICAL CONSIDERATIONS

Gastro-intestinal hemorrhages which can be traced to a ruptured aneurysm of the hepatic or cystic artery or varix, or a vessel eroded by a decubitus ulcer or an ulcerating lesion in the gall bladder require no comment. The same is true of bleeding based on a hemorrhagic tendency due to jaundice, or malignant disease of the biliary tract.

Several hypotheses have been advanced to explain the occurrence of bleeding in gall bladder disease where a bleeding point is not demonstrable. It has been claimed that venous thrombosis may cause hemorrhage, that gastric ulcers may be embolic in origin, that toxins in the blood from chronic infection in the gall bladder may cause bleeding from the stomach and upper bowel as it does in essential hematuria or epistaxis, that hepatitis may be the underlying factor. The failure of recurrence of bleeding following removal of the gall bladder points to the gall bladder itself. The effects of vomiting and retching cannot be ruled out. However, cases have occurred with no retching. Violent vomiting in other conditions is not attended by massive hemorrhages from the bowel. In some cases the vomiting is probably induced by the presence of blood in the stomach.

Bleeding into the gall bladder may occur by seepage in a diffuse phlegmonous or hemorrhagic process. Infarction of the entire wall may occur. Bleeding into the bowel occurs if the cystic dust is patent.

Bleeding attending the formation of a cholecystoduodenal fistula may be a minor incident in the history, may even be entirely unnoticed.

The symptomatology if cavernomatous transformation of the portal vein may simulate cirrhosis of the liver or peptic ulcer. Jaundice may supervene.

Jaundice may complicate duodenal ulcer. The causes may be intercurrent catarrhal jaundice or mechanical cicatricial closure of the papilla of Vater. Obstructive jaundice may become associated with ulceration of the upper bowel.

DIAGNOSTIC FEATURES

In the presence of jaundice differentiation must be made between bleeding due to a general bleeding tendency or a local cause. Without jaundice, the cause is usually a local one. It is important to remember that gall stones may be accompanied by a massive hemorrhage. Though the bleeding source may not be demonstrable, removal of the stone-containing gall bladder promptly relieves the bleeding, as a symptom. This also rules against the probability of a missed peptic ulcer.

Parenchymal liver degeneration may be associated with frank bleeding into the duodenum. Blood was obtained by transduodenal drainage in such a case. Malignant disease of the biliary passages may thus be simulated and laparotomy performed in a case of subacute yellow atrophy.

Occult bleeding may occur in gall bladder and liver disease, though the presence of blood in the stool usually favors the diagnosis of peptic ulcer or malignant disease.

The incidence of gross bleeding in one to five per cent of our patients with gall bladder disease, in a carefully observed material confirms the estimates of other authors.

COMMENT

The massive hemorrhages occurring in individuals suffering from gall stones, without duodenal ulcer demonstrable by X-ray or laparotomy are remarkable. In some instances a history of previous hematemesis or melena may be obtained yet no cholecystoduodenal fistula can be demonstrated. Laparotomy performed soon after a hemorrhage may reveal no ulceration due to passage of a stone. It is conceivable that a superficial gastric mucosal erosion may escape the most careful search. Vomiting or a toxic factor may be responsible. Appendicitis or peritonitis has been known to be complicated by massive hemorrhage on the basis of gastric erosion, toxic in origin.

SUMMARY

Local types of gastro-intestinal bleeding associated with disease of the liver and biliary tract have been distinguished from the systemic.

Hematemesis and melena may occur in conditions other than peptic ulcer, ruptured oesophageal varix or ulcerating malignant disease of the biliary tract.

Frank hemorrhage into the intestinal tract may occur in degenerative lesions of the liver parenchyma (liver atrophy), in aneurysm of the hepatic artery, and in hemorrhagic disease of the gall bladder if the cystic duct remains patent. Bleeding into the upper bowel may occur in gall stones without jaundice and without a demonstrable bleeding point. This bleeding does not recur following cholecystectomy.

Occult bleeding may occur in disease of the liver parenchyma as well as in non-malignant disease of the biliary tract.

ABSTRACTS

CLINICAL MEDICINE

GOLDMAN, JOEL, AND COHEN, ABRAHAM.

Abdominal Distention in Lobar Pneumonia. Ann. Int. Med., IX, 1222, March, 1936.

In discussing the origin of gases in the intestinal tract the authors make clear that they are interested in those gases which are not readily absorbed, such as hydrogen, nitrogen and methane, *though admitting that other gases* may accumulate in the intestinal tract in a rate of formation in excess of their rate of absorption. In discussing the origin of intestinal gas, Cutting is quoted, in which he held that the origins were (1) composition of food stuffs, (2) diffusion of gas from the blood stream, (3) swallowed atmospheric air. He went on to discuss their production by stating that one source was from the action of bacteria on sugars in the lower portion of the small intestine; (2) the action of bacteria on cellulose residue remaining undigested; that free hydrogen occurred in the blood stream under pressure of 4/5 of an atmosphere, *while oxygen and carbon dioxide occurred* in chemical combinations only. The nitrogen is left free to leave the blood stream to replace other gases in the intestine when pressure relationships are favorable, whereas in order for oxygen or carbon dioxide to leave the blood stream there must not only pressure relationships be disturbed, but also must conditions be favorable for the liberation of these gases from their chemical combination. Alvarez is quoted as stating that little or no trouble was experienced from flatulence in a series of patients at the Rochester Clinic suffering from pneumonia when treated in a chamber containing 50 per cent of oxygen, because in such an atmosphere more of the nitrogen in the bowel could diffuse out. The consensus of opinion of authors consulted in the preparation of the paper appeared to warrant the conclusion that putrefactive and fermentative changes in the intestines were of minor importance as compared to disturbances in the diffusion of gases and that an additional embarrassment of the *circulation resulted from* chemical interference with the splanchnic circulation or perhaps also from compression of the heart through the *diaphragm; that in abdominal* distention it was thought that gaseous distention depended chiefly upon alterations in the interchange of gases between the gastro-intestinal tract and the blood. Thus the normal equilibrium of these gases could be upset by disturbances in the toxicity and motility of the gastro-intestinal musculature or by interference with the local fixation. In *pneumonia* possibly the diminished capacity of the lung may thus be in part responsible for the distention commonly associated with that disease.

A discussion of the drugs that have been recommended to be used to combat distention of this nature follows, with the conclusion that none of them was satisfactory in all cases. Impressed by the report in 1933 of Paine, Carlson and Wangensteen, describing a form of continuous lavage of the duodenum by means of a nasal tube to relieve postoperative distention, nausea and vomiting, the authors introduced a modification of this apparatus to be used in the management of abdominal distention in *lobar pneumonia and other conditions* producing distention. The modification of the continuous lavage of the duodenum consisted in its application to rectal suction siphonage. The only difference in the apparatus used by the authors and that described by Paine and his associates was the substitution of a soft rubber rectal tube for the Levine duodenal tube. The technique of its use consisted in giving a cleansing soapsuds enema before the apparatus was set in action and an attempt to keep the stools in a liquid state to prevent block of the tubes. This latter desideratum is obtained by the use of saturated magnesium sulphate solution. The use of the apparatus was continued as long as necessary to reduce the distention and discontinued so soon as the distention was relieved, and was repeated whenever necessary. The only untoward effect was tenesmus. The authors treated 100 cases and report control of distention in less than 24 hours in most of the cases, only 18 per cent requiring a longer period for control. Rectal irritation occurred in 13 per cent; in 34 per cent the distention was controlled notwithstanding a fatal termination. It was concluded the procedure gave added rest to the patients, that the need of bed-pan disturbance was reduced, the nursing problem was simplified, that it could be carried out in the home as well as in the hospital, that incontinence was infrequent and that it is safe, inexpensive and effective.

RATTNER, H.

Stomatitis Due to Sensitization to Dental Plates. J. A. M. A., Vol. 106, pp. 2230-2232, June 27, 1936.

Stomatitis due to sensitization to material in dental plates is a condition not generally recognized by dentists or physicians. The author presents three cases who developed stomatitis after changing their dental plates or having their old ones repaired with new materials.

The severest of the cases was characterized by burning tongue, excessive salivation, soreness of the mucous membranes of the entire oral cavity, nausea, eructations and a thick discharge from the mouth occurring towards the end of the day. Examination revealed a markedly inflamed mucous membrane with serous exudation. The other cases were of less severity. In two of the cases there was a positive patch test where the plate was applied to the arm.

The composition of the material from which dental plates are made is a trade secret, but enough is known about them to indicate that they contain substances which may be irritating to susceptible cases.

MENTZER, STANLEY H.

Obstructive Cholecystitis. S. G. O., Vol. 62, No. 5, May, 1936.

The author discusses Obstructive Cholecystitis with particular reference to acute obstructive cholecystitis and its sequelae. He discusses the progressive steps in the pathology of acute obstructive cholecystitis to empyema which is the eventual outcome. In this connection he points out that the mortality in the treatment of acute cholecystitis will be decreased if the obstructive lesions are differentiated, clinically, from the non obstructive. Dr. Mentzer

BILE SALTS

Fairchild

The sodium glycocholate and taurocholate, the salts of conjugated colic acids in their native association as separated from fresh ox gall.

A stable dry powder; uniform in composition; efficient for the well known therapeutic uses of ox-gall—in disorders due to faulty bile functioning.

Bile Salts preferably to be dispensed in capsule by itself, or in combinations in powder.

Offered in powder, ¼ oz., 1 oz. vials; in capsules, each three grains Bile Salts.

Fairchild Bros. & Foster
New York

is of the opinion that acute cholecystitis that cannot be differentiated clinically, should be operated upon within 6 to 48 hours after the patient enters the hospital.

In dealing with nomenclature applied to gall bladder pathology, the author suggests that the term "Acute Obstructive Cholecystitis" be applied to the suddenly obstructed and acutely inflamed gall bladder which is still filled with bile. The adjectives fibrinous, phlegmonous, and gangrenous may be added to define the pathological condition further, if desired. The terms "hydrops" and "empyema" are used to designate the obstructed gall bladders, filled with mucus or pus. Acute and subacute exacerbations of these are indicated by these adjectives.

The progression of the pathological condition from acute obstructive cholecystitis to hydrops and finally to empyema is dependent upon the time element and upon the presence of old or recent infection. If these could be determined clinically, the type of obstructive disease might be anticipated. It is usually impossible, however, to determine which colic, if any, resulted in complete obstruction and it is even more difficult to decide when the onset of fresh infection has occurred. Under these circumstances, it is not surprising that so few correct pre-operative diagnoses of the exact stage of the process are made.

Dr. Mentzer thinks it is unfortunate that surgeons too often content themselves with a diagnosis of acute cholecystitis and then treat the patient conservatively to await subsidence of the acute infection. In his own experience the mortality with excessive conservatism was 56%. This has been reduced by more accurate diagnoses and by earlier surgical intervention to 15% in obstructive cholecystitis. Their mortality with perforated gall bladders with delayed operation was 55% in 1932 and with early operation 41%. At present it is 44 and 11% respectively.

He states that if the acute cholecystitis is so marked that abdominal rigidity prevents the palpation of a mass and therefore prevents us from differentiating the obstructed from the non-obstructed forms of acute cholecystitis, as well as inhibiting the differential diagnosis of the three types of obstructive cholecystitis, then we should observe the patient for 6 to 48 hours before instituting surgical therapy. If fever, leucocytosis, tenderness, and rigidity have not definitely subsided in this period, surgical exploration should be done for we know we are dealing with an advanced, acutely inflamed gall bladder. Under this policy, the author states, their mortality has decreased.

The author reviews 149 consecutive gall bladder operations performed on the University of California service at the San Francisco Hospital in the past 6 years; 51 of these were for obstructive cholecystitis. Most of the obstructive lesions were encountered in women (72%) and the major number of the patients were in the age group 40 to 60 years. Eight per cent of the patients having hydrops, 12% of those having empyema and 30% of those having acute obstructive cholecystitis states that they had never suffered from any symptoms that might be even suggestive of previous cholecystic disease. The temperature curves were highest in the empyema cases and lowest in the hydrops. Jaundice had not been observed by any of the 10 patients who had acute obstructive cholecystitis and only 2 of the 24 who had hydrops had had any icterus. Neither of these groups had jaundice with the present illness. Of the 17 having empyema however, 6 were icteric while in the hospital.

Most of the operations performed on the 51 cases of obstructive cholecystitis were cholecystectomies but the author feels that, even at that, an unduly high percentage, 35% were cholecystostomies. The author feels that cholecystostomy is often the operation of choice, particularly in the aged, debilitated, and very ill, but when done, it should be remembered that a cholecystectomy will probably be necessary later.

MARTIN, KIRBY A.

Histidine Hydrochloride Versus Diet and Alkalis in Treatment of Peptic Ulcer. J. A. M. A., Vol. 106, p. 1468, April 25, 1936.

Histidine was first used by Weiss and Aron of Strasbourg in 1933. They based their work on experimentally produced ulcer by the Mami-Williamson technic, which was treated by the injection of histidine. Since the use of this substance began, there have been many favorable clinical reports concerning its efficacy in the treatment of peptic ulcer in human subjects. Because of these reports, a series of 41 selected patients with acute symptoms and radiologic signs of peptic ulcer were treated with the substance.

The histidine was given intramuscularly. All but three of the patients were kept ambulatory, and their diets were not changed. The immediate response to this therapy was prompt and uniform. Thirty of the patients were relieved of their symptoms at or before the conclusion of the treatment. Fourteen of these showed X-ray evidence of a healed ulcer and twelve showed a crater still present. Eleven showed no improvement.

The patients were observed for from six months to one year. At present, thirteen are symptom free and twenty-six have had relapses. Of the twelve rendered symptom free, but in whom a crater persisted, only three have remained symptom free, whereas of the fourteen rendered symptom free in whom no crater could be demonstrated, ten have remained so.

A second, or control group of 40 similar cases was selected and put upon the diet-alkali regime. At the end of four weeks, a period corresponding to the histidine treatment, thirty-one were symptom free. They were observed for one year. Sixteen have remained symptom free and twenty-six had relapses.

The symptomatic and radiologic response of the patient in the histidine series was not quite as good as that in the diet-alkali regimen series, in either the initial or the sustained effects.

The clinical improvement following histidine therapy appears to be symptomatic and transient. Histidine merely alters the rhythm of the course of peptic ulcer. It showed no constant effect on the secretion of hydrochloric acid in this series. The indications for histidine hydrochloride therapy are limited and results are not as good as previously thought.

Regional Enteritis (non-specific). S. G. O., Vol. 62, No. 6, pp. 977-988, June, 1936.

The authors report a series of eight (8) cases of regional enteritis seen during the last two years. The path-

My Clinical Records Tell Me . . .

In the use of clinical records for gastro-enterological work, you are enabled to discuss with your patients their individual conditions and secure their co-operation for best results from your medical treatment.

Where cases of constipation, hepatic insufficiency, either functional or in association with early cirrhosis, catarrhal and other forms of jaundice (provided the bile ducts are not completely obstructed), bilious attacks, prevention and treatment of gall stones, intestinal auto-intoxication, indicate the advisability of a step up in the flow of bile, prescribe or dispense

TAUROCOL TABLETS
or Taurocol Compound Tablets

These products have been effectively used by the medical profession over a period of a quarter of a century.

We will be pleased to send you clinical record forms upon request.

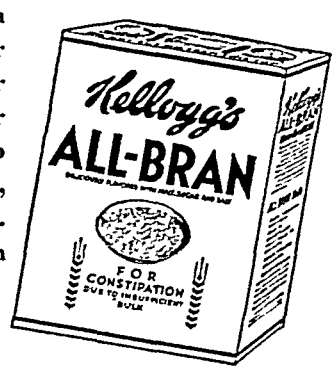
If you are not now prescribing or dispensing Taurocol or Taurocol Compound, write for literature and samples.

TAUROCOL *Compound* TABLETS
ARE A COMBINATION of TAUROCOL WITH DIGESTIVE FERMENTS INDICATED IN AUTO-INTOXICATION

THE PAUL PLESSNER COMPANY
3538 Brooklyn Ave.
Detroit - Mich.

J. D. 8-36

His trouble started



A LONG TIME AGO

SO MANY people have no real idea of the cause and effects of common constipation. Frequently, they treat it too lightly and develop a run-down condition. Their lowered resistance may be the first step to serious illness. Then only do they see the doctor. Others try to dose themselves — often with harmful results.

If they could only be impressed with the fact that constipation is usually due to insufficient "bulk" in meals. Its correction is largely a matter of proper diet Kellogg's ALL-BRAN is a pleasant, convenient source of gentle "bulk." It is not broken down in the body as much as the "bulk" in fruits and vegetables. So ALL-BRAN is often more effective.

Scientific tests have shown that Kellogg's ALL-BRAN is a natural laxative food for normal people. It may be served as a cereal with milk or cream; sprinkled over soups, salads, or other cereals; or cooked into muffins, breads, waffles, etc. Sold by all grocers. Made by Kellogg in Battle Creek.

The natural food

THAT CORRECTS CONSTIPATION

due to insufficient "bulk"

ological process may be divided into three stages: (1) acute regional enteritis. (2) chronic hypertrophic enteritis with stenosis of the lumen, and (3) chronic enteritis complicated by external or internal intestinal fistula. The process is usually sharply demarcated at the ileocecal valve and may or may not end abruptly at a point proximal to the ileocecal valve. A thickened edematous mesentery may indicate perforation between its leaves and may be an indication as to treatment to be followed. Abscesses in the mesentery may rupture into other loops of bowel or into the colon to establish a fistula.

The symptoms of regional enteritis may be divided into four groups according to Crobu: (1) segus of an "acute surgical abdomen," (2) symptoms of ulcerative colitis, (3) symptoms of chronic obstruction of the small intestine, and (4) persistent intestinal fistula following drainage of an abdominal abscess. The symptoms in one-half of the author's cases simulated acute appendicitis. Recurring colic-like intermittent pain of acute intestinal obstruction was present in three of the cases. No case had a history of diarrhea. A moderate leukocytosis was present. Roentgen ray examination of the gastro-intestinal tract is entirely negative, or shows a filling defect in the terminal ileum. In the advanced cases the string sign of Kantor may be seen.

The treatment of acute regional enteritis depends on the stage of the process. If the mesentery is not involved and there is no obstruction, conservative treatment may be chanced. If the mesentery is thickened and edematous, or there is a fistula present, wide resection of the diseased parts is necessary.

Eight cases are reported in detail. Fourteen figures accompany the article.

Nelson M. Percy, Chicago.

ALVAREZ, W. C.

Severe Gastric Hemorrhage Produced by Violent Abdominal Massage. J. A. M. A., Vol. 107, p. 124, July 11, 1936.

Severe exertion involving the abdominal muscles may produce a gastric hemorrhage in patients with peptic ulcers. The case here reported is that of a man who had had symptoms of a duodenal ulcer since eleven years of age. He placed himself in the hands of an irregular practitioner who placed a large electrode on the lower abdomen and sent through him a rhythmically interrupted current which caused severe contraction of the abdominal muscles. He became severely distressed and vomited up large quantities of blood. He was almost completely exsanguinated, and had to be transfused several times. From this it is obvious that abdominal massage, or excessive use of the abdominal muscles is contraindicated in peptic ulcer.

EXPERIMENTAL PHYSIOLOGY

BOLLMAN, J. L., AND MANN, F. C.

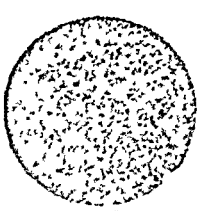
The Influence of the Liver in the Formation and Destruction of Bile Salts. Amer. Jour. Phys., 116, No. 1, 214-224, June, 1936.

The authors using the method of Gregory and Pascoe studied bile salts in bile, urine, and blood under various conditions. They find that in the normal dog bile salts are not detectable in the blood and urine; on intravenous injection of glycocholates or taurocholates, only a small amount is recovered in the urine and feces, while they disappear from the blood quite rapidly. With complete hepatectomy, bile salts are not detectable in the blood and urine; and injected salts are practically quantitatively recovered in the urine within twelve hours. With complete biliary obstruction bile salts increase in the blood and urine; the bile salts in the blood remain markedly increased for about two weeks and then drop to a low, but detectable level at which they remain, urinary output of bile salts

Help Step Up The Appetite DURING PREGNANCY

The critical period of pregnancy and lactation increases the demands made upon the mother's bodily resources by the developing fetus. She needs a highly nutritive diet, which imposes the least possible strain upon her unstable digestive apparatus—food which pleases the palate and will be readily assimilated.

Here is where OVALTINE serves as a valuable dietary adjunct. OVALTINE is a homogeneous pure food concentrate, prepared in vacuo from high diastatic malt extract, milk and eggs. Among other reasons it is recommended because:



1. It is light, easily digested, and increases the ease of digestion of milk on account of the formation of fine, soft curds.
2. It has appetite and taste appeal. Due to its Vitamin B content it helps build the desire for other foods.
3. It supplements the diet with essential proteins, fats, carbohydrates, vitamins, iron and the bone-forming elements, calcium and phosphorus. It is a good source of Vitamins A, B, D and G.
4. It is well adapted for between-meals feeding as it is easy to prepare.

As a Galactagogue

Clinical experience over many years has conclusively shown that OVALTINE has specific galactagogue properties. As the result of its use a marked improvement in the flow and quality of the milk generally follows.

remains fairly constant throughout the course.

Intravenous injection of bile salts in animals with complete obstruction, results in increased urinary excretion, but recovery is about 60% as compared to 95-100% in hepatectomized dogs. Urinary output of bile salts in animals with complete obstruction is one-half to one-third the amount excreted by animals with biliary fistulae. Hepatotoxins markedly diminished the bile salt level in blood and urine in these animals as well as in the bile of bile-fistula dogs. The authors conclude that the data is evidence of hepatic production and also destruction of bile salts, and that hepatotoxins alter the process of formation.

BETTMAN, RALPH BOERNE, AND TANNENBAUM, WILLIAM J.

Gall Bladder Contractility After Blood Transfusion. J. A. M. A., Vol. 106, pp. 1376, April 18, 1936.

Ivy was the first to isolate cholecystokinin from the mucosa of dogs and demonstrated that the contractility is initiated by a hormone. Sandblom apparently proved that this hormone is transmitted by the blood by showing that in fasting individuals the gall bladder contracted after receiving blood from a donor who had previously eaten a fat meal.

Bettman and Tannenbaum selected nine healthy individuals, gave them a breakfast high in fat content and withdrew blood from them in an hour and a half after the ingestion of the meal.

A patient who had a normal concentration of dye in the gall bladder and normal emptying of it, but who also had one calculus, was selected. The gall bladder dye was given in the evening, and in the morning the film showed a large distended gall bladder and good concentration. One hundred cubic centimeters of high lipoid serum was given and X-rays taken ten minutes, one-half hour, one hour and two hours later showed no emptying. After two hours the usual fat meal was given, and a film taken one hour afterward showed normal emptying.

A similar experiment was tried with the transfusion of whole blood with the same results.

The conclusion was reached that neither high lipoid content serum or whole blood transfusion from a patient who has recently had a fatty meal will cause contraction of the gall bladder.

MILLER, D. K., AND RHODES, C. P.

The Effect of Liver Extract on the Small Intestine of Patients with Sprue. Am. Jour. of the Med. Sci., p. 453, April, 1936.

A clinical study of a group of patients with sprue was made and it was observed that flatulence, intestinal discomfort, cramps and diarrhea recurred unless a sufficient amount of liver extract was given frequently. The intestinal dysfunction was independent of the anemia and larger quantities of liver were necessary for its control than for that of the anemia. This suggested a relationship between liver extract and intestinal activity.

Characteristic morphological alterations of the small intestine of patients with sprue were found by X-ray studies and consisted of: 1, a segmental distribution of barium, produced, it is inferred, by abnormal motility of portions of the small intestine; 2, a variation of contour and caliber of the intestinal segments; 3, a distorted mucosal pattern, especially of the duodenum and jejunum, but often of the ileum as well; 4, an outline of the terminal ileum which appears straighter than normal and gives the impression of a lack of pliability of the intestinal wall. The authors report a case of

IN SALT-POOR, LOW FIBRE, RESTRICTED DIETS

Your dietary injunctions in a variety of abnormal conditions, both functional and organic, present this annoying corollary problem: How to maintain adequate intake of the protective minerals and vitamins?

Properly-cooked sieved vegetables, unseasoned, are of course an answer to this question—but ordinarily *only* at the cost of much time and nuisance on the part of those caring for the patient—and even then with considerable *doubt* on your part as to the nutritional values being adequately retained until the patient actually ingests the vegetables!

Therefore, may we draw your attention to the following brief facts about how Gerber's strained vegetables solve this problem:

All Gerber's vegetables are (a) raised from pedigreed seed (b) in selected soils (c) under strict supervision (d) picked at sunripeness (e) rushed to inspected kitchens for prompt cleansing and (f) Shaker-Cooking (g) in *closed* systems, under controlled temperatures, with only vacuum evaporation of moisture, the better to conserve vitamin and mineral values — and (h) packed *un*-seasoned to await your instructions.

Gerber's

Shaker-Cooked Strained Foods
STRAINED TOMATOES, GREEN BEANS, BEETS, CARROTS, PEAS, SPINACH, VEGETABLE SOUP. ALSO, STRAINED PRUNES AND CEREAL.

Professional samples gladly sent you at your request
Also a supply of booklets giving therapeutic-diet receipes to help patients with the "palatability" factor.

Easy to take

KONDREMUL

(Chondrus Emulsion)

THE PLEASANT BOWEL CORRECTIVE

The emulsion of mineral oil with Irish Moss in the form of Kondremul is not only effective in the treatment of constipation, but also pleasant to administer.

To suit the individual needs, three Kondremul types provide effective range of treatment:

KONDREMUL WITH PHENOLPHTHALEIN -- laxative and regulative.

KONDREMUL WITH CASCARA -- combines the tonic laxative action of non-bitter cascara with the soft bulk of Kondremul.

KONDREMUL PLAIN -- inert -- may be used with utmost safety as a regulative in children as well as adults.

sprue exhaustively studied and followed for three years. She was gravely ill. Under large doses of liver extract intramuscularly, her profound anemia improved, there was a reticulocyte response of 42% and in 7 weeks her r.b.c. were 4,170,000 and hgb. 73%. Diarrhea, which was present before treatment was begun, was immediately checked but recurred if a longer period than two weeks elapsed between injections of liver extract. Roentgenray examinations made in the presence of diarrhea and after its cessation demonstrated that the segmental distribution of the barium throughout the small intestine and a residue of barium in the stomach for 6¾ hours with the diarrhea gave place to a smooth continuous outline of the barium throughout the small intestine and the stomach was empty in two hours.

Summary: 1. Roentgenologic evidence of abnormal form and function of the small intestine of a patient with sprue, without anemia but with diarrhea is presented.

2. A return toward normal form and function, as evidenced by roentgenologic study, as well as the disappearance of symptoms followed the injection of liver extract.

3. It is suggested that liver extract administered parenterally conditions the functional activity of the small intestine.

Allen Jones, Buffalo.

BLOTNER, HARRY.

Effect of Alcohol on Digestion by Gastric Juice, Trypsin and Pancreatin. J. A. M. A., Vol. 106, 23, June 6, 1936.

The author had previously found that alcohol prevented the digestion of insulin by gastric juice, trypsin and pancreatin, and it appeared that alcohol had either destroyed or inactivated the enzymes. Since an *in vivo* inactivation of enzymes in drunkards might help to explain their neuritis on the basis of a food deficiency state, Blotner carried his experiments further. Normal gastric juice freshly collected failed, when mixed with suitable amounts of alcohol, to digest egg white in any degree, and results were the same when commercial trypsin and pancreatin were tested in the same way. Blotner went further and tested the proteolytic activity of aspirated gastric juice from persons recovering from prolonged bouts of heavy drinking and found that the proteolytic activity of the juice was absent. He noted, however, that these samples contained no free HCl, and proceeded to add HCl to the samples but still obtained no digestion of coagulated egg-white. He concludes that "considering the chronic alcoholic patient with polyneuritis or deficiency disease, it would appear that the large quantities of liquor taken over a long period of time destroys digestive enzymes and thus prevents the proper digestion and assimilation of food." Such a conclusion is scarcely justified in the sense in which the author means it. It is not unusual to find an achlohydria in an alcoholic but there is no proof that the patients pancreatic secretion is either absent or inactivated.

THE CONTINUOUS DRIP TREATMENT OF PEPTIC ULCER Becomes A Simple Routine With The NEW *Creamalin* AUTOMATIC DRIP CONTROL

The continuous drip method in the treatment of peptic ulcers was suggested by the desirability of constant neutralization of the excess hydrochloric acid, night and day. Excellent results, as evidenced by roentgenological examination, have been reported. • • The continuous drip treatment requires a neutralizing agent that has high combining power and that can be administered in large volumes without toxic effects, and a simple, dependable apparatus for maintaining the continuous drip. • • **THE CREAMALIN AUTOMATIC DRIP CONTROL** facilitates the technique of the drip method of administration. The solution drips into the patient's stomach, via a Levine tube, without quantitative or qualitative change, day and night. The apparatus is compact, sturdy, easy to operate, and requires a minimum of attention. • • Creamalin, a specially prepared cream of colloidal aluminum hydroxide, is especially suitable as the neutralizing agent in the continuous drip treatment. It possesses the necessary combining power, **combining with 14 volumes of tenth-normal hydrochloric acid by physical fixation in one hour.** Creamalin is miscible with water and will not cause clogging in the apparatus. A pint of Creamalin diluted with three parts of distilled water can be administered every 24 hours as a continuous drip without disturbance to the acid-base balance and without toxic effects of any kind. • • Creamalin has been administered orally with satisfactory results, but it has produced its most spectacular results by the continuous drip method, especially in refractory cases. A number of these were bleeding peptic ulcers and others were cases where surgical intervention had been contemplated. • • In one institution alone 62 cases have been treated by the Creamalin Drip and, with one exception, x-ray evidence indicated healing of the ulcerated area within seven to ten days. • • Write for further information and material for clinical trial.

CLEVELAND CHEMICAL ASSOCIATES • • • CLEVELAND • OHIO

ceal attack. The attacks subsided and he was seen three months subsequently with symptoms suggesting gastric ulcer. The symptoms were controlled by ulcer regime. In January, 1934, he developed another attack of acute abdominal pain accompanied by hiccoughs. At that time the white blood count was 15,000. One week later the attack subsided. In March he was admitted to the hospital for a gastro-intestinal X-ray study. The stomach was of the cascade type and contained a large amount of residue. Numerous fluid levels were seen in the large and small bowel. At times, during the fluoroscopic examination, it seemed that an ulcer niche could be made out on the posterior wall of the stomach in the region above the incisura angularis.

Films revealed the presence of a fleck which led to the diagnosis of an ulcer on the posterior gastric wall. The appearance of the distended colon with multiple fluid levels suggested lower bowel obstruction. For this reason a barium enema was done one week following the oral meal. Again the fleck was seen in the same position as it was one week before. As no barium nor bismuth had been given the patient during the interval, it was concluded that a small gastro-colic fistula existed which permitted the ulcer niche to fill during the enema examination. Upon the basis of this diagnosis an exploratory operation was performed and no pathology was found by the surgeon. The appendix was removed and the patient made an uneventful recovery.

On November 1st, after feeling well during the interval, the patient had a recurrence of upper abdominal pain and vomiting. The fluoroscopic examination was unsatisfactory because of vomiting. The patient went into shock and died. At postmortem, the abdomen was found to be filled with straw-colored fluid. The intestines were matted together by a plastic exudate. An abscess was found in the left upper abdomen in a curve of the distal transverse colon. This abscess developed from two perforated jejunal ulcers, which were opposite each other, one on the posterior and one on the anterior wall, and were located four inches from the duodenal-jejunal junction, and there were enlarged soft lymph nodes along the mesenteric attachment.

Pathological report revealed no evidence of malignancy.

Primary ulcers in this part of the bowel are quite rare and more rarely still is the diagnosis made before operation.

D. S. Beilin, Chicago.

SURGERY OF THE LOWER COLON AND RECTUM

ARENA, JAY M.

"Pyloric Stricture Following the Ingestion of Muriatic Acid." South. Med. Jour., 29:331-333, March, 1936.

Esophageal obstruction following the ingestion of lye is a rather familiar picture. Lye, because of its greater concentration over the epithelial lining of the esophagus, does its great corrosive action there and, when diluted in the stomach, is relatively harmless. Acids, on the other hand, produce only a scorching effect on the esophageal mucosa, and then concentrate their effects in the region of the pylorus—even, at times, when taken in small amounts and low concentration. This scarring, which is usually slower in producing symptoms, may lead to rather complete obstruction. Its possibility should be realized and symptoms carefully looked for after acids are taken—otherwise these symptoms may be confused with other factors. An interesting recovery in a child of two years following a Finney pyloroplasty is reported in the article.

J. Duffy Hancock, Louisville.

KNOX *Clinical* NOTES

SO many informative letters from practicing physicians reach my desk concerning the wide adaptability of gelatine in therapeutics, Knox Gelatine in particular, that I am presenting to you a few of the suggestions submitted.

■

A New Jersey pediatrician writes that he has been using Knox Gelatine with satisfactory results for children who show lack of muscle tone. He insists on Knox Gelatine because it is high in glycine content. Knox Gelatine contains over 25% of this amino-acetic acid.

■

A Virginia doctor writes relative to the use of Knox Gelatine in muscular dystrophies. He says, "we have been getting some very nice results from it." The recommended dose of glycine for the treatment of muscular dystrophy and myasthenia gravis is 10 to 15 grams daily. This can be supplied by giving Knox Gelatine in palatable recipes containing as high as 10% of the product.

■

A Tennessee medical man tells us that in almost all asthenic conditions, especially muscular, whether the cause can be diagnosed or not, and regardless of other treatment and diet, he has the patient use Knox Gelatine in this manner: One of the four little envelopes (containing ¼ ounce) taken from a package of Knox Gelatine is dissolved in a little warm water. The glass is then filled with cold fruit juice and the patient drinks it at once. This gives almost 2 grams of glycine.

■

A new brochure entitled "Glycine Therapy in Muscular Dystrophy and Myasthenia Gravis" is now available. This contains, in addition to useful recipes, abundant clinical references, colored and plain illustrations of muscle-tissue involvement and other interesting material. Request a copy. Simply write to Knox Gelatine Laboratories. 475 Knox Avenue, Johnstown, N. Y.

For bland diet therapy, especially ULCER cases—PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastro-intestinal disorders is a deficient diet. An analysis made by Troutt of ulcer diets used by 6 leading hospitals in different sections of the country showed them to be "well below the Sherman standard of 15 milligrams" in iron and low in the water-soluble vitamins.[1] "Vitamin B would appear to be represented at a maintenance level in most cases," writes Troutt, "but the possible relation of vitamin B to gastro-intestinal function and appetite should make one pause before accepting a low standard."

Although Pablum has a low fiber content it is 37 times richer than farina in iron and in calcium, 4 times richer in phosphorus, and 4½ times richer in copper.

Low in Fiber—High in Iron

Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastro-intestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than farina and is an excellent source (+ + +) of vitamins B and G, in which farina is deficient. Supplying 8½ *mgms.* iron per ounce, Pablum is 8 times richer than spinach in iron.

Rich in Vitamin B

The high vitamin B content of Pablum assumes new importance in light of recent laboratory studies showing that avitaminosis B predisposes to certain gastro-intestinal disorders. Apropos of this, Cowgill says, "Gastric ulcer is another disorder which can conceivably be related to vitamin B deficiency. Insofar as the treatment of this condition usually involves a marked restriction of diet the occurrence of at least a moderate shortage of this vitamin is by no means unlikely."[2]

Requiring no further cooking, Pablum is especially valuable during the healing stage of ulcer when the patient is back at work but still requires frequent meals. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Pablum has the added advantage that it can be prepared in many *varied ways—in muffins, mush, puddings, junket, etc.* Further, Pablum is so thoroughly cooked that its cereal-starch has *been shown to be more quickly digested than that of farina, oatmeal, cornmeal, or whole wheat cooked four hours in a* double boiler (studies *in vitro* by Ross and Burrill[3]). In addition to the above advantages, Pablum is the only base-forming cereal (except Mead's Cereal which is the uncooked form of Pablum).

Pablum (Mead's Cereal thoroughly cooked) consists of wheatmeal, oatmeal, cornmeal, wheat embyro, alfalfa, yeast, beef bone, iron salt and sodium chloride. [1-3] Bibliography on request.

EXICOL

INDICATED in hepato-biliary disorders when dependable cholagogue and choleretic action is desired.

In prescribing Exicol you have the advantage of an effective therapeutic agent checked in the animal laboratory and clinically.

Exicol therapy is based on latest known and accepted physiologic principles governing the biliary apparatus.

ACTION: 1. It stimulates gall bladder evacuations (Cholagogue) and
2. Increases bile flow from the liver (Choleretic).

DOSE: 2 capsules t.i.d.a.c.

In boxes of 36 and 100.

until gastrostomy was performed the patient lost 85 pounds (38.6 kg.); following insertion of the tube, however, he regained 25 pounds (11.3 kg.). In spite of the pronounced dysphagia, fluids would occasionally pass from the esophagus into the stomach.

Roentgenoscopic and esophagoscopic examination revealed cardiospasm (Fig. 1). Dilatation of the cardia and closure of the gastric stoma relieved the patient of his symptoms.

Case 2. A man, forty years of age, was examined August 8, 1933. In December, 1932, he had been ill with influenza for about three weeks. About the time he was able to be up he was injured in an automobile accident and suffered considerable trauma over the abdomen, associated with the vomiting of blood. A week later he vomited a large amount of blood. This was repeated three days later, and then, for two or three weeks, he noted tarry stools. By the first of April, 1933, he was able to be out of bed, but soon after this he noted a burning pain in the epigastrium associated with hiccoughs and obstruction to solid food in the lower portion of the esophagus. The pain soon disappeared but the dysphagia became more pronounced.

Examination revealed a benign stricture in the lower portion of the esophagus (Fig. 2). Dilatations were carried out and, at the end of the last treatment in December, 1935, the patient was eating normally and his general condition was excellent.

Case 3. A woman, sixty-six years of age, was well until June, 1921, when she suffered a severe injury in a railroad wreck. Several ribs were fractured, and there was considerable abdominal pain associated with the passage of blood by bowel. Following this accident the patient continued to have attacks of epigastric pain which was projected substernally to the neck and lower jaw. Two months later occasional obstruction to food at the cardia was noted.

The dysphagia very gradually became worse and at the time of her *first examination* at this Clinic, in October, 1931, a diagnosis was made of cardiospasm (Fig. 3). Dilatation of the cardia was followed by almost complete relief from dysphagia, but the attacks of pain, although not so severe or so frequent, continued until the time of the patient's last examination in April, 1936.

Case 4. A man, twenty-nine years of age, who had previously been in excellent health, was in an automobile accident April 4, 1936. He was struck in the chest by the steering wheel. Immediately following this he suffered severe substernal pain which was increased on respiration; there were cough and expectoration of bloody sputum, and the temperature rose to 102 to 104° F. Five days after the accident the patient began to have difficulty in swallowing, and any attempt at ingestion of fluids was followed by severe attacks of coughing. A Rehfuss tube had been introduced for feeding.

The patient was brought to this Clinic for *examination* two weeks after the accident and his condition on admission was quite critical. He was coughing up large amounts of foul, purulent sputum and had a continuous fever, with rapid respiration and an increased pulse rate. *Roentgenographic examination* of the thorax revealed the tube in the stomach; there was a large angulated section of the tube that apparently had passed through the esophageal wall (Fig. 4). From this finding it was concluded that perforation of the esophagus had occurred and that the tube was protruding into the mediastinum. Sudden terminal hemorrhage occurred two days after admission.

Postmortem examination revealed a longitudinal rupture, 1½ inches (3.7 cm.) long on the anterior wall of the esophagus and the posterior wall of the trachea (Figs. 5 and 6). This rupture communicated with the mediastinum and gangrenous mediastinitis was present. There was very little evidence of external injury.

A Study of the Hippuric Acid Excretion as a Test of Hepatic Function*

By

K. G. KOHLSTAEDT, M.D.

and

O. M. HELMER, Ph.D.

INDIANAPOLIS, INDIANA

THE measurement of hepatic function is especially difficult because of the tremendous reserve capacity of the liver and because of the multiplicity and interrelation of its functions. When the change is within the limit of the physiological reserve of this organ, the determination of the amount of hepatic damage cannot be measured with any degree of accuracy by the majority of the clinical tests now in general use. Tests measuring carbohydrate metabolism or excretory function may be entirely normal even when the physiological detoxification mechanism may be markedly impaired. It is in only the most severe and advanced instances of hepatic damage that we are likely to find all functions of the liver impaired to an equal degree. The detoxification mechanism of the liver is one of the more important functions of this organ, as failure of this mechanism may produce metabolic dysfunction in other organs of the body.

In 1933, Quick (1), who studied the detoxication of noxious substances by conjugation with glycine, presented a method for testing the detoxifying function of the liver. Following the work of Bryan (2), Quick devised a clinical test in which sodium benzoate was administered orally and the amount of hippuric acid excreted in the urine during a four-hour period determined. After the work of Bunge and Schmeideberg (3), and until recently, the site of the conjugation of sodium benzoate and glycine was believed to be in the kidney. These investigators used dogs in their experiments but Quick (4) repeated their work using

rabbits. He believed that in man, as in the rabbit, the site of the conjugation, as well as the site of the synthesis, of glycine is in the liver.

Bryan was the first investigator to report the use of sodium benzoate as a liver function test but he was primarily interested in its use as a kidney function test. Quick (1, 5) reported two series of cases of various types of liver disease which were studied by means of the hippuric acid test. Vaccaro (6) reported a series of 44 cases and Snell and Plunkett (7) reported a series of 38 cases. The results published in all of these reports indicate that this test furnishes an accurate and reliable method of testing the detoxifying function of the liver. Although Quick described

two methods, all of the other investigators used only the simple clinical method in their series of cases.

Since the rate of excretion of hippuric acid depends on the kidney function as well as on the rate of synethesis of glycine and its conjugation, it is necessary to measure kidney function in these cases. Quick suggested the determination of non-protein nitrogen as a control for kidney function because hippuric acid behaves like other nitrogenous excretory products. In some cases in our series urea clearance was substituted for non-protein nitrogen determination since it was found that this test is a more delicate control for the hippuric acid excretion.

METHODS

5.9 gm. of sodium benzoate was given orally in a half glassful of water at 8 a.m. Breakfast was limited to coffee and plain toast. Quantitative urine specimens were collected at hourly intervals for 4 hours. At first four separate determinations were made, but later the specimens were pooled and a single determination was made.

These determinations were carried out exactly as outlined by Quick (1). Although the precipitation of hippuric acid by the addition of concentrated hydrochloric acid gave good results in most cases, the second method described by Quick, in which the hippuric acid is removed from the specimen by means of the continuous ether extraction method, offers some advantages which are of great practical value. These advantages are: (1) the presence of bilirubinuria does not interfere with the test; (2) the long, tedious concentration of specimens is eliminated; (3) small amounts of hippuric acid can be determined. In addition to the technical advantages of this method, a urea clearance test can be performed with the same specimens used for hippuric acid determination because after the volume has been determined only 10 c.c. of the total specimen is used for extraction, leaving the rest of the specimen for the urea clearance test. Van Slyke's (8) method was used for the urea clearance determinations.

RESULTS

Table 1. This group of 9 cases showed *no evidence of hepatic pathology.* The first 7 cases were studied by means of the extraction method and in the other 2 cases the precipitation method was used. All of these cases gave results within the limits of normal as established by Quick (1) and the other investigators (6, 7). The extraction method gave results similar to those obtained by the precipitation method.

Case 7 is of especial interest because this case presented all the symptoms of cholecystitis although surgical exploration of the abdomen revealed no evidence of pathology. However, the excretion of hippuric acid was within normal limits.

Table 2. This table includes a group of 6 cases of *definite cirrhosis* with hepatic enlargement and ascites. None of the cases in this group showed serologic evidence of syphilis.

Two determinations were made in Cases 10 and 12 at varying intervals. Case 11, who had alcoholic cirrhosis, was studied for a period of 3 years. The first

two determinations were made by the precipitation method and the last by the extraction method. The results obtained in this case corresponded in every way with the clinical course. The second determination was made at the end of several months' hospitalization and the final observation was made 16 months after his release from the hospital. Clinically, the patient had regressed to the same level as at the time of the first determination.

Case 15 was operated upon because it was thought there was common duct obstruction. However, postmortem examination showed that the only pathology present was a marked cirrhosis. With a normal urea clearance in this instance the low hippuric acid output must be attributed to the extensive liver damage. In this case, the precipitation and titration method would have been very inaccurate as due to the very low output the amount of precipitate would have been very small, and the marked bilirubinuria would have made titration impractical. Death in this instance was a typical "liver death" due to failure of liver function postoperatively.

Table 3. This is a *group of cases affected with syphilis* and varying degrees of hepatic involvement. Two determinations were made in Case 16. The second was made 2 months after the first and, although the jaundice had greatly decreased, there was only a negligible increase in the output of hippuric acid. This would indicate that the decrease in jaundice does not necessarily indicate a similar improvement in liver function. This finding has been noted by both Quick and Vaccaro.

It is interesting to compare the histories of Cases 17 and 18. In each instance the patient became jaundiced following a single injection of neoarsphenamine. In Case 17 the liver function was normal and the history revealed that the patient had acquired syphilis only a few months previously. However, Case 18 gave a history of having been jaundiced following previous treatment and his syphilis was of several years' duration. In the latter case there was a lowered liver function with definite widespread liver damage, but in Case 17 the jaundice was probably due to an acute arsenical hepatitis of very recent origin.

In this group the results vary from limits of normal to 0.9 gm., the total four-hour output indicating the great variation in amount of liver damage produced by hepatic syphilis.

Table 4. This group is composed of cases of *malignant tumors* with widespread hepatic involvement as evidenced by clinical studies. All of the 4 cases which came to autopsy showed extensive metastases. Case 31, who was deeply jaundiced and whose liver function was extremely low, was operated for carcinoma of the head of the pancreas. After a stormy convalescence following a cholecystogastrostomy the patient recovered and at the present time is engaged as a furniture mover. Twenty months after his release from the hospital the patient returned for another liver function test and the output of hippuric acid was found to be normal. This patient had a reduced liver function as the result of prolonged obstructive jaundice but when the obstruction was relieved the detoxification mechanism returned to normal.

The results in this group were, on an average, the lowest of any obtained in this series.

Table 5. In this group are 22 cases of *disease of the biliary tract,* all of which were operated upon. The test results varied widely. In cases with normal liver function the postoperative reaction was mild and recovery was uneventful. Two deaths occurred in cases with low liver function. In each instance the clinical syndrome could be described as typical hepatic failure terminating in "liver death." A third death occurred

TABLE V

This is a group of cases of extrahepatic biliary disease, all of which were operated. The diagnosis given is the final diagnosis. The Wassermann was negative in all cases but Case 42

in a case with only moderate liver damage but which was complicated by syphilis. Other cases operated upon when there was low liver function recovered, but in all of these cases the convalescence was exceedingly stormy and accompanied by hyperpyrexia with nausea and vomiting. The results indicate that the severity of this postoperative reaction increases as the output of hippuric acid decreases.

In Cases 41, 43 and 44 tests were made after the patients had completely recovered from surgery. In none of these cases had the hepatic function, which had been lowered preoperatively, returned to normal. The excretion of hippuric acid had decreased in one instance. These results would indicate that in cases of cholelithiasis and cholecystitis surgery offers a much greater risk when there is evidence of an impaired detoxicating mechanism as shown by the hippuric acid test. Furthermore, surgical removal of the gall bladder does not serve to restore pre-existing hepatic damage, although it may serve to eliminate a source of furthering this damage.

Table 6. This group consists of 4 cases of *catarrhal jaundice.* All of these patients recovered, and the diagnosis was made from clinical study. As the precipitation method is considered very inaccurate in these

TABLE VI

All of these cases were diagnosed clinically as catarrhal jaundice and made uneventful recoveries. There was no history of lues or antiluetic treatment and the Wassermann was negative in each case

						0.988	Ext.	

severely jaundiced individuals all of these cases were studied with the extraction method.

Case 60 is particularly interesting because by chance this patient had had a hippuric acid test 3 months before the jaundice developed. At the time the first test was taken the liver function was normal but during the acute attack of typical catarrhal jaundice there was a marked reduction in excretion of hippuric acid.

Table 7. This is a small group of patients with *toxemia of pregnancy*, in all of which the hippuric acid output was reduced. The severity of clinical symptoms seemed to bear a definite relationship to the degree of liver damage as measured by this test. When the test was repeated during the post-partum period in Cases 66 and 67 each of these showed a marked increase in hippuric acid excretion. However, this problem is very complex and these results indicate only the need for further study of the hepatic detoxifying mechanism during pregnancy.

Table 8. This table includes a variety of *miscellaneous cases*, in each of which there was a decrease in urea clearance. Some of the patients showed clinical evidence of hepatic involvement plus renal damage, but others showed renal dysfunction only.

In Case 69 malignancy with metastasis to the liver was the preoperative diagnosis. Although nitrogen retention was not present the urea clearance was greatly reduced. The reduced hippuric acid output was probably due to poor renal function, as in surgery the liver appeared normal grossly and only a fibroid of the uterus was removed. Cases 72 and 76 showed no nitrogen retention and in Case 75 there was only slight retention, but the lowered urea clearance and the decreased hippuric acid output indicate the necessity for combining these two tests. Case 77 showed that nephritis alone without liver damage is capable of reducing the output of hippuric acid. Furthermore, there was no evidence of nitrogen retention, although the urea clearance was very low.

DISCUSSION

The fact that the urea clearance test can be combined with a liver function test so that both liver function and kidney function can be studied on the same urine specimens, increases the value of both tests to the clinician. The urea clearance is a better control for the hippuric acid test than is the simple measurement of nitrogen retention, because, as stated by Van Slyke, *et al* (9), "it is only when the renal function, as measured by the urea clearance, has fallen to less than 20% of normal that a great part of the blood urea

TABLE VII

This is a group of cases of toxemia of pregnancy. In Cases 66 and 67 tests were taken during both the prenatal and post-partum periods. In none of these cases was there jaundice, hepatic enlargement, or a positive Wassermann

concentrations become definitely elevated." (See Case 77).

This *combined liver and kidney function test* offers an added safeguard in the preoperative study of surgical cases, because postoperative complications which may result in the so-called "liver death" are most likely to occur in those cases in which the hepatic detoxifying mechanism or the renal function is impaired. The exact mechanism which brings about the syndrome terminating in "liver death" with its accompanying disturbances in metabolism is unknown. However, the fact remains that there is a combined failure of hepatic and renal functions in these cases. Helwig and Schutz (10) suggested that the pathogenesis of this syndrome depends primarily on some intracellular hepatic damage. They believe a toxin is the causative factor and that this toxin may be produced by a perversion of functions of the damaged liver cells or by a lack of the proper physiological detoxifying ability of the cells. This failure of hepatic detoxification would thus permit the accumulation of substances which are toxic to the kidney. The presence of a low four-hour output of hippuric acid with a normal urea clearance would indicate that the liver is unable to synthesize sufficient glycine during this period. However, when the urea clearance is less than 50% of normal the diminished output of hippuric acid may be due to kidney damage as well as to hepatic damage. When there is a low hippuric acid excretion or low urea clearance the case should be considered a poor surgical risk, especially when the surgery would involve the extrahepatic biliary system.

The tests described are of equal importance to the internist in his study of diseases of the liver. A knowledge of the degree of impairment of the detoxifying mechanism of the liver is essential whenever the use of hepatotoxic drugs is contemplated. As shown by Wile and Sams (11), the low incidence of jaundice in untreated syphilis (0.18%) as compared with that (1.37%) following arsphenamine treatment indicates the high degree of hepatotoxicity exerted by this drug. Posttherapeutic jaundice is most likely to occur in cases in which there is pre-existing damage of the detoxifying mechanism as indicated by the hippuric acid test. A low output of hippuric acid would therefore be a contraindication for the use of arsphenamine in the usual manner.

The hippuric acid test offers also a means of determining the progress of cirrhosis and of other diseases of the liver. This test is a more accurate method of determining the recovery from hepatic disease with jaundice than is the determination of the serum bilirubin. This variation between the rate of disappearance of jaundice and the recovery of the detoxifying ability, as previously reported by Quick, is borne out by studies made on the cases in this series.

The results reported in the present series of cases are similar to those obtained by the other investigators. However, the hourly determination of hippuric acid is not of great clinical value and for general use the single determination of the total four-hour output is sufficient.

SUMMARY AND CONCLUSIONS

1. The hippuric acid test was used in a series of 77 cases. The results indicate that there may be a marked reduction in the detoxifying ability of the liver before

any of the clinical signs of hepatic disease can be detected.

2. The simultaneous determination of the urea clearance increases the value of the hippuric acid test.

3. The ether extraction method with the formol titration is the most practical as well as the most accurate method of determining the hippuric acid in the urine.

4. The combined urea clearance and hippuric acid test is a reliable and valuable adjunct in the study of hepatic disease.

Note: The authors wish to thank Dr. L. G. Zerfas and Dr. G. H. A. Clowes for their interest and advice.

The Relation of Gastric Acidity to the Erythrocyte Content of the Blood*

By

FRANK L. APPERLY, M.A., M.D., D.Sc.

and

M. KATHERINE CARY

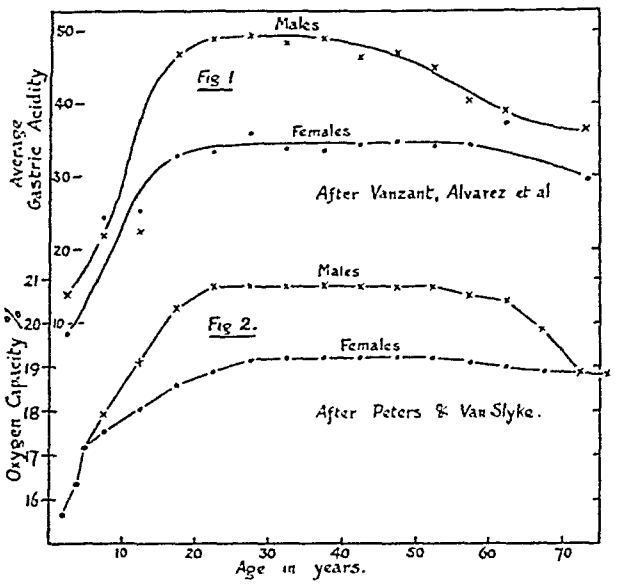
RICHMOND, VIRGINIA

IN 1931 it was shown by Apperly and Crabtree (4) that the concentration of hydrochloric acid in the human stomach after a test-meal was regulated by the CO_2 content of the plasma of the fasting subject. This was found to be true not only when the plasma CO_2 was artifically varied in the subject of experiment, but also when different normal individuals were compared. A recent survey of all available clinical data relating to conditions in which plasma CO_2 varied within and beyond the normal limits has entirely confirmed the above experimental results. (Apperly, 1936) (3). Among these is the group of anoxemic conditions, of which anemia has special interest.

It has long been felt that anemia tends to lower both gastric acidity and plasma CO_2. Our preliminary experiments, however, showed us that in anoxemia, gastric acidity was considerably lower than could be accounted for by the fall of plasma CO_2. It appeared that anoxemia was of itself able to lower gastric acidity, and even result in achlorhydria. This raised the question, viz. Is there an anemic achlorhydria in contrast to the achlorhydric anemia of Witts? These considerations led us to investigate gastric acidity over a wide range of red cell content of blood.

A. *Relation of gastric acidity to red cell content of blood in normal people.*

The first interesting fact that we noticed was the striking similarity between the graph representing the average gastric acidities for different age and sex groups (as determined by Vanzant, Alvarez, *et al* (11) from 3746 cases), (Fig. 1), and the graph showing the average hemoglobin content of the blood for similar age and sex groups (from Peters and Van Slyke) (10), (Fig. 2). When the figures from these two series of observations are plotted against each other a straight line relationship is revealed, (Fig. 3). There is, of course, a considerable individual scattering about these average curves. These charts suggest two things: (a) That variations in average gastric acidity for different age and sex groups are at least partly dependent on hemoglobin differences, or whatever causes the latter, and (b) That, assuming the straight line in Fig. 3 continues as such to the base line, gastric acidity disappears when the hemoglobin of the blood falls to an average of about two-thirds its normal value; that is, that anemia can bring about achlorhydria. These figures, however, show us the relationship of gastric acidity and hemoglobin only over the range found in normal people. What happens in anemia and polycythemia?



B. *Relation of acidity to red cell content in hemorrhagic anemia.*

For our study of gastric acidity in anemia we chose afebrile cases of recent and chronic hemorrhage, since it appeared to us that these were of the simplest type, uncomplicated by hypochromia, toxic or other factors of which the effects were unknown. In all cases red cell volume (hematocrit) and gastric acidity at one hour (gruel meal of 400 c.c. and Rehfuss tube) were determined in the resting and fasting patient on different occasions, e.g. on admission, during hospitalization and sometimes after discharge. As Fig. 4 shows, although the acidity is far from being the same in different individuals with the same erythrocyte volume, in all cases acidity rises with increase in red cell volume. In some cases achlorhydria accompanied the lower erythrocyte levels. (Three cases with gastric symptoms and high acidity referred to later are omitted from Fig. 4).

In all examinations the blood was drawn from the median-basilic vein under oil to prevent loss of CO_2 and therefore changes in pH and red cell volume. It was then defibrinated by the technique of Eisenmann

(shaking with mercury without contact with air) and centrifuged for one hour at 3000 revolutions per minute in the hematocrit tubes of Shock and Hastings. This speed gives constant readings after 40 minutes.

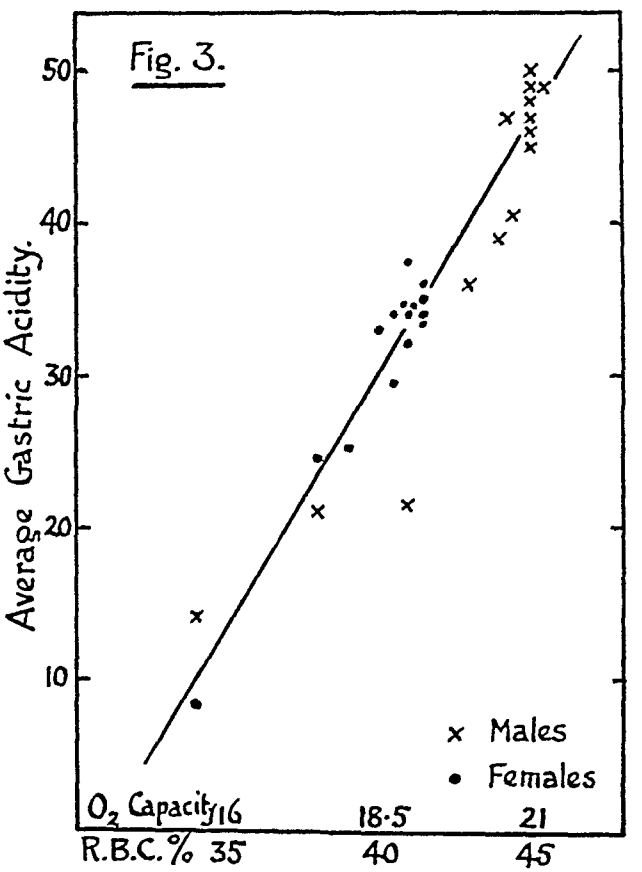
C. *Relation of acidity to red cell content in polycythemia.*

Our own figures from cases of polycythemia in man are too few to make definite generalizations. Our four cases, however, all have a low acidity (Fig. 4). If this is typical, then it would appear that at, or just beyond the normal hemoglobin content the acidity curve falls again. There is very little record in the literature of the relationship of polycythemia to gastric acidity and what there is mostly relates to these conditions in association with duodenal ulcer. The following appear to have most bearing on our problem:

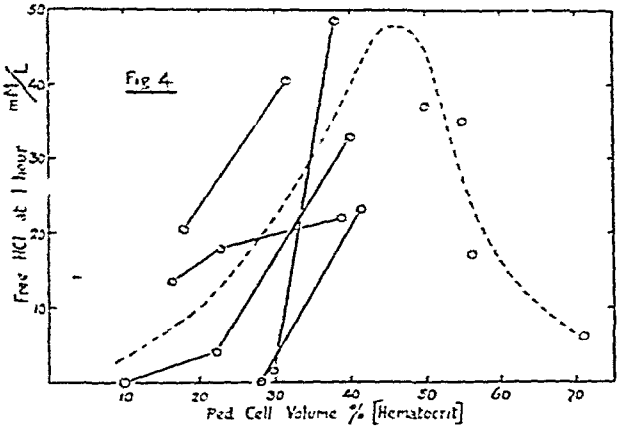
a. Wilbur and Ochsner (12) examined the gastric acidity in twenty-five cases of polycythemia of which five had duodenal ulcer. The figures of each case are not given, but of the non-ulcer cases, the acidity in sixteen fell within normal limits, and in four there was hypochlorhydria or achlorhydria. All of the five ulcer cases, however, showed hyperchlorhydria, one rising to a free acidity of eighty.

b. Friedman (5) has collected twenty-seven cases of duodenal ulcer with polycythemia in all of whom there was a hyperacidity which increased with increasing polycythemia.

c. Lerman, Pierce and Brogan (9), in a series of two hundred patients with no gastric symptoms showed a steady rise of acidity with red cell count up to seven millions. They used a meal of fifty c.c. of 7% alcohol and a simultaneous injection of 0.5 mgm. histamine, so that beyond their general effect these results can hardly be compared with the ordinary test-meal figures.



d. Fouts, Helmer and Zerfas (6) have published a number of cases of anemia of different types in which red cell counts, hemoglobin and the *highest* titratable acid are recorded, but no relationship was disclosed. The work of the authors quoted in the preceding paragraphs and our own experience indicate that these relationships are only revealed when the acidity in each case is determined at the same time, e.g. at one hour, after the ingestion of the test-meal, and not at that time at which the acidity is at its highest.



The work quoted above at first sight seems to be conflicting. We can divide the various cases into two groups, viz. (1) Those polycythemic patients with no gastric symptoms who were tested by the Ewald or gruel meal. In these the acidity was normal or low (our own four cases: Wilbur and Ochsner's twenty cases), (2) Those polycythemic patients who had, in addition, duodenal ulceration (the groups of Friedman and the remaining five cases of Wilbur and Ochsner). In these cases acidity continued to rise with increasing polycythemia.

From the above somewhat scant evidence then, it will be seen, when we put aside all cases complicated by peptic ulcer or other gastric abnormalities and consider only those remaining cases in which the same bland test-meal was employed (such as that used by Alvarez, Wilbur and ourselves) that with increasing polycythemia gastric acidity falls. Since, however, this evidence is so meager, we decided to carry out experiments on dogs.

D. *Experimental observations on anemia and polycythemia in dogs.*

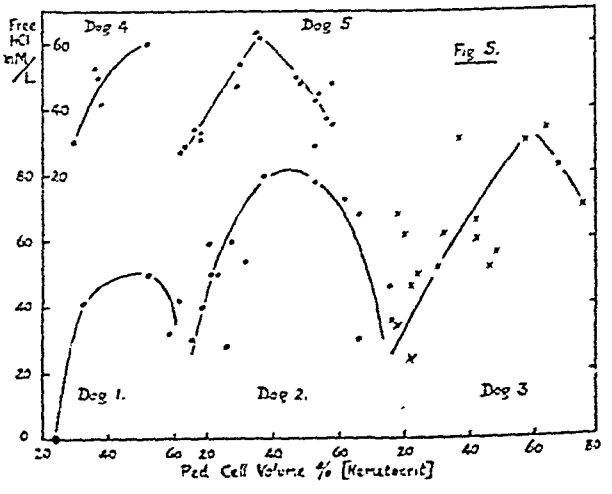
Observations were made on five dogs in which anemia and polycythemia were produced by bleeding and transfusion. In order not to alter significantly the blood volume or osmotic pressure by these procedures the following technique was used. Sufficient blood was drawn in several fractions from the femoral artery to produce the required amount of anemia. The serum was then centrifuged from the cells, made up to a slightly greater volume than the original whole

blood and reinjected into the animal within an hour of bleeding. To produce polycythemia the cells were suspended in as little saline as compatible with a slow flow by gravity, and injected into another animal. The dogs were kept on a constant diet of prepared food (Purina Chow) containing all the necessary vitamins and minerals. Under this regime they lost no weight and were lacking in energy only at the lowest cell volumes (below 18%). At the very highest cell volumes (70% or more) there was a tendency to a mild diarrhea, somewhat blood streaked. This disappeared within 48 hours after the cell transfusion.

In dog 5, there were exceptions to this routine. In order to prevent the rapid regeneration of blood on the stock diet, which necessitated very frequent bleedings, this dog was kept on a bread, milk, and cod liver oil diet during the anemic phase. This enabled us to make several determinations at any blood level. A few meals of stock diet would raise the blood level and allow study at the next level.

Two days were allowed after bleedings or transfusions for the blood electrolytes to settle to a new equilibrium. Blood was then drawn from the jujular vein, treated as in section B, above, and the hematocrit volume determined. The Rehfuss tube was then passed into the stomach, the dog lying quietly on its back, or left side, fasting contents withdrawn and a volume of 5% alcohol in water (9 c.c. per kilo) run into the stomach. Samples were withdrawn every fifteen minutes for titration of free acid.

The results of these experiments are shown in Fig 5. It will be seen that in every case gastric acidity at 30 minutes after the alcohol "meal" rises with erythrocyte content of blood to a maximum at a point somewhat above the normal erythrocyte content. Beyond this point gastric acidity falls. These results then are in keeping with those found in man as described above.



In presenting these results we should add some comments. Certain conditions which we could not always explain or control occasionally caused exceedingly rapid or slow emptying of the stomach, with consequent changes in acidity. We feel justified in using the data only from those experiments in which the emptying time was "average" and rejecting the extremes, i.e. those with emptying time of less than 45 minutes and more than 90 minutes. We also rejected a few cases when an excessive regurgitation of bile occurred in animals in which some bile did not habitually appear. The first three tests on all dogs were also discarded, because we felt that the restlessness and nervous apprehension accompanying the unaccustomed technique caused the achlorhydria usually found. Further, in the first few experiments small dogs were chosen in order that the desired degree of anemia or polycythemia could be produced by the withdrawal or transfusion of smaller volumes of blood, but the small size of the arteries and veins in these animals presented an almost insuperable obstacle. Consequently in these cases (Dogs 1 and 4) only a few points are plotted. Of themselves they would have little significance, but they are presented as additional evidence to the more complete curves obtained from the other dogs. In one animal (Dog 3) of highly excitable temperament, used during the late summer and early fall, when the temperature was very variable and respiration obviously affected, the points are very scattered on the anemic end of the curve. Those on the polycythemic end, taken later at a more constant temperature and with no exciting factors (such as visitors or a strange attendant) show however the usual configuration.

E. *The incidence of achlorhydria in anemia and polycythemia.*

If our thesis is correct, viz. that the highest acidity in any individual accompanies a normal red cell content, but diminishes with increasing anemia or polycythemia, then we should expect to find in any group of people a higher incidence of achlorhydria among those with anemia and polycythemia, the achlorhydria incidence increasing with increasing severity of these conditions. This has indeed already been demonstrated by Lerman and Means (8) and by Alvarez (2). These observations therefore support our own work.

F. *Relation of gastric acidity to red cell content of blood in association with gastric abnormality.*

It is well known that gastric acidity is regulated by, among other factors, duodenal regurgitation. Anything which interferes with this, e.g. pyloric spasm, or the over-rapid hypertonic stomach, results in hyperacidity. Under these circumstances we would expect, even in severe anemia or hyperchlorhydria, an acidity higher than that normally corresponding to the red cell content of the blood. The work of Friedman (5) and of Wilbur and Ochsner (12) quoted in section C. above shows that this is so. This has also been the experience of Hurst (7), Alvarez (1) and ourselves. Among our cases there were three (bleeding duodenal ulcer: pylorospasm: nervous hypermotility) in all of

whom there was, in spite of severe anemia, a marked hyperacidity. With improvement in the blood condition acidity in all three rose still higher. With eventual disappearance of symptoms in the case of duodenal ulcer the acidity fell to a "normal" figure at the third examination. It will be recalled that higher acidities were also found in one of our dogs (dog 3) when a nervous hypermotility was associated with the presence of strangers in the laboratory.

SUMMARY AND CONCLUSIONS

These observations show that:

(a) When, as a result of recent or chronic hemorrhage, the red cell content of the blood falls below a certain critical level, free acid disappears from the stomach. Our results in a few cases in man indicate that this level is, on the average, about one-third to two-thirds the normal. In dogs the critical level is much lower. We have no information concerning gastric acidity in anemias of other origins.

(b) Above this critical level gastric acidity rises with erythrocyte content to a maximum when the latter somewhat exceeds that found in normal health, i.e. in man, a hematocrit volume of 46%.

(c) With increasing hematocrit volumes above about 50%, in man and dogs, acidity steadily falls again to low figures.

(d) From the above we would expect a rising incidence of achlorhydria with increasing anemia and increasing polycythemia. This has been shown to be so by several observers.

(e) When severe hemorrhagic anemia is associated with peptic ulcer, pylorospasm or certain other gastric conditions, acidity values are found to be far higher than those with a corresponding degree of anemia without gastric abnormality.

(f) Our experiments show that in certain conditions where anemia is associated with achlorhydria, the entity which we have called anemic achlorhydria must be considered in addition to Witts's achlorhydric anemia and pernicious anemia.

Note: We are indebted to the Richmond Dairy Co. for the donation of the milk used in the dog experiments.

The Intestinal Rate, Normal Nutrition, and Health:

New Principles for the Maintenance, Restoration, and Control of Health

By

FRANCIS LOWELL BURNETT, S.B., M.D.*

BOSTON, MASSACHUSETTS

INDIGESTION, MALNUTRITION AND DISEASE

"THE wonder is not that structural imperfections and functional disharmonies should develop in proportion to our numbers, but rather that so many of us escape harm altogether and enjoy good health. . . The solution of our problem of life is a fuller knowledge of the use and working of those parts of our bodies most apt to give way under our modern ways of living—the use of such structures as the great bowel. And when we have replaced our ignorance by real knowledge, we shall be in a position not to adapt our bodily structure to our mode of living, but our mode of living or our bodily structures. . . The great bowel is not a useless or superfluous organ, but one which we in our ignorance are maltreating" (1).

Such an assertion intimates that intestinal indigestion, malnutrition and ill health may be revealed by a better understanding of the functions of the colon from right eating; and they may be corrected by an exact means to determine the absorption of food; for "little is known concerning the difficulties of absorption and utilization of food products from the digestive tract, and regarding what particular foods may improve gastro-intestinal function. . . It is probable that significant degrees of such disturbances may arise in arthritis, and be overcome by well chosen diets" (2).

Obviously, eating too fast and too much, irregularly, incomplete or disproportioned meals, or the frequent use of laxatives, etc., are not conducive to the maintenance of normal nutrition and health. But when "we adapt our mode of living to our bodily structures" by the correction of these erroneous ways, a delicately adjusted and complex function of the colon begins to operate, which moulds the intestinal contents entirely

*Director of Health Class for Skin Diseases at the Massachusetts General, and Assistant in Charge of Health Class for Arthritis at the Peter Bent Brigham Hospitals.

Submitted May 19, 1936.

into the uniform segments of the normal feces. In this way the digestive system acts as a perfect nutritive apparatus, because this function serves to determine wrong eating, and perhaps erroneous ways of living. Again, as this function moulds the normal feces, it also measures the contribution made one meal to the construction of the body, or the normal intestinal rate;* and thus these indices denote the complete digestion and absorption of the food (3). Then, as nutrition is the sum of the processes by which an animal absorbs, utilizes, and takes in food substances, and assimilation is the final and most important phase of the process (4), the indices of absorption still further serve to determine normal nutrition, and to furnish a clue to the construction and maintenance of cells. For by the application of these indices to nutrition, erroneous ways of eating not only provoke a previously unrecognized kind of intestinal indigestion and malnutrition, but also give rise to a formerly obscure cause of disease. This is because they result in a course, incomplete, and disportioned alimentary mixture, which induces an abnormal action of the colon, by which soft and formless feces and rapid intestinal rates are produced. In these circumstances nourishment goes *through* instead of *into* the body, and the relatively unknown condition of an exact and improved state of well being from normal or anabolic nutrition cannot be maintained. In such a disorder there is a failure in the final and most important phase of nutrition—assimilation—and the weak skin, bone, or some other tissue of a patient breaks down in a recognized metabolic disease. After some of these diseases, as indigestion, acne, eczema, psoriasis, or arthritis have been diagnosed, principles of treatment for the creation and control of this state of health to cure them, have been applied with good results (5, 6, 7, 7b).

THE CREATION OF ANABOLIC OR NORMAL NUTRITION

The correction of intestinal indigestion and malnutrition from this point of view, is brought about by teaching patients how and what to eat and how to live, so that their nutritive apparatus produces normal feces and normal intestinal rates. In carrying out these principles, an enquiry of the patient's ways of eating is first made, and one or more unhygienic habits are invariably revealed. And an examination of the feces at this time often confirms some of these erroneous ways of eating. Then, an explanation of the normal and abnormal operations of the nutritive apparatus with diagrams and descriptions of the normal, formed, and soft types of the feces with illustrations, are given. As a supplementary aid in learning the subject, a printed outline of the principles and practice, and a form to follow in keeping a record of nutrition, is presented to each patient. Again, the health measures advised, such as "to chew food thoroughly and eat dinner at night," or "to omit laxatives, eat fruit at lunch and dinner, and try to deject twice," are written out on a sheet for the patient to use for a record of his nutrition: and the supplementary measures to relieve symptoms are prescribed. After the patient has written out the food consumed, the time spent at meals, the time and kind of dejections, and a test of the intestinal rate, in a week's record, he returns to the office or health class with one often beginning like Record 1.

Record 1

Health measures to improve: eat slowly and dinner at night; also omit laxatives, eat fruit at lunch and dinner, and try to deject twice.

Thursday, September 27, 1934

6:30 to 6:50 p.m., beef broth, steak, beans, beets, toast, apple sauce, cake.

7:00 p.m., charcoal taken to mark this meal.

Friday

7:45 to 8 a.m.; egg, toast, coffee.

9:15 a.m., soft dejection with first charcoal; *initial intestinal rate, 14 hours.*

12:15 to 12:35 p.m., fish chowder, crackers, apple pie.

6:30 to 6:55 p.m., potato soup, cod, lima beans, broccoli, roll, peaches, cake.

Saturday

7 a.m., soft dejection with charcoal.

8 to 8:20 a.m., oatmeal, egg, toast, coffee.

1 to 1:20 p.m., vegetable soup, crackers, carrots, prunes, cake.

6:15 to 6:40 p.m., bouillion, chicken, potato, squash, spinach, roll, plum tart.

Sunday

8:30 to 8:50 a.m., creamed toast, fish ball, coffee.

10 a.m., soft dejection with last charcoal; *final intestinal rate, 63 hours.*

1:30 to 2:05 p.m., beef, potato, parsnips, cauliflower, roll, raspberry ice, cake.

6:30 to 6:50 p.m., cheese souffle, vegetable salad, roll, cocoa, peaches, cookies.

Monday

7:30 to 7:45 a.m., egg, corn bread, coffee.

9 a.m., soft dejection without charcoal.

12:30 to 12:50 p.m., omelette, potato, blueberries, cake.

6:45 to 7:15 p.m., beef, sweet potato, corn, peppers, toast, apple betty.

Discussion of Record 1:

The dejections noted by the patient in his first record are generally of the soft type; and the marked evening meal in passing through the nutritive apparatus in 14 to 63 hours, signifies a rapid intestinal rate. The former erroneous ways may have caused an irritable colon and malabsorption; but some foods should be increased and others should be reduced. Accordingly, still more health measures are advised, such as "to eat many vegetables and sparingly of meat, cereal foods and fruit"; and these are written out on a second sheet for a record of his nutrition. These measures should be adopted immediately, but another week's record may not be examined for two weeks. At this visit the patient generally feels better, although he may have lost a few pounds; but he has had some formed instead of soft dejections, and his intestinal rate has become a little more extended to one of about 14 to 85 hours. These changes indicate that a better alimentary mixture has begun to improve the action of the colonic functions and the absorption; and now the consumption of a small breakfast and lunch may be advised, in order still further to improve the utilization of food. These changes are shown in Table I.

From now on the patient should be seen every few weeks in order to observe his condition and weight.

*The intestinal rate is determined by the ingestion of 25 to 50 c.c. of French millet seeds or 100 grains of charcoal immediately after an evening meal; and then the number of hours that elapse from the time the marker was taken to the time when the seeds or charcoal are first and last seen in the feces, is observed. In adults producing segmented feces, one and sometimes two dejections are common daily, yet the marked evening meal takes about 62 hours to appear in, and 134 hours to disappear from the feces; and this rate is considered normal. (Burnett, F. L.: *Am. J. Roentgenol.*, 10:359, 1923).

but more particularly to examine records of his nutrition; for unless he presents records showing one or two normal dejections daily, and rates of 38 to 110 hours or better, his alimentary mixture is not refined enough, and the health measures must be carried out more precisely. As the intestinal rate is the most exact means to determine normal nutrition, all patients are advised to make this test and to weigh the body every few weeks; and those who carry out these requirements, have normal rates, and change little in weight, can be seen infrequently. At one of these visits, an examination of the patient's blood for anemia or hypoglycemia, or tests for other conditions, can be made.

THE CURE OF DISEASE BY THE CREATION AND CONTROL OF AN IMPROVED STATE OF WELL BEING

The results obtained from the education of about a thousand patients with symptomatic indigestion, acne, eczema, psoriasis, arthritis, or some other disease, to restore health from anabolic nutrition, have been gratifying; because when the principles of treatment are understood and cooperation of the patients is secured, the diseases are almost invariably relieved. To be sure, the improvement in the health of chronic invalids is always slow, and months and sometimes years of treatment are required before tangible results become evident. The results obtained in the treatment of all of these diseases are very similar; therefore, definite figures of those compiled in a recent study of arthritis (7), may be used for this purpose.

In this study, an attempt was made to educate 241 patients in these principles of treatment, over a period of five years. Of this number, 74 were private and 167 charity patients; but there were 34, in the latter group especially, who were unable to understand the practice of anabolic nutrition, and there were 89, who by a failure to bring in more than five records or to be observed for more than five months, were considered uncooperative; and the patients of these groups have been excluded in an appraisal of the treatment. Of the remaining 118 patients, 45 became healthy, in as much as they were free of pain and swelling in the joints, and enjoyed a normal sphere of activity, and 73 became better. Some of these became healthy subsequently by more prolonged treatment; and 7 of this number made an attempt to learn anabolic nutrition once and failed, then took up treatment again after remaining the same or becoming worse for a year, and have improved. Details of the results of treatment in a few patients with arthritis, and other diseases are shown in Table I.

When disease is relieved by the creation of an exact state of health, it is obvious that a recurrence must be prevented if the disease is to be cured. All persons are human and are likely to digress from the even and sometimes dull tenor of healthy living; and such digressions if of short duration and infrequent, may not be injurious when a reserve of health has been established. To prevent a recurrence of disease in these former patients, it is necessary to know from time to time how well they carry out the requirements of anabolic nutrition, in order to remain healthy. To this end, all of those instructed in the principles of treatment are advised to observe every dejection and to keep them normal, and to make a test of the intestinal rate and to weigh the body every few weeks, and

record them. Then, several times a year according to the supervision required, they are asked to bring in records of their nutrition. The response to such a request is shown in Record 2. And at one of these visits, a comprehensive and exact examination of the body and various specimens can be made, to assure these persons of good health. A few of the patients who were restored to health, and then failed to carry out the requirements to control their health and prevent a recurrence, are shown in Table II.

TABLE II

The recurrence of disease in healthy persons from a failure to control health from anabolic or normal nutrition

Initials of Patients	Age	Sex	Disease and Its Duration	Erroneous Ways, Excesses or Deficiencies of Food Consumption	Condition, Weight, Feces and Intestinal Rate (Listed Consecutively)		Comments on the Causes of the Recurrence of Disease
					1st week	2rd to 4th years	
A. M. S.	25	F.	Psoriasis, 9 yrs. and arthritis, 1 yr.	Laxatives +, fat +, cereal foods +	Same, 186 lbs. Formed, 56-111 hrs.	Well, 178 lbs. Normal, 51-124 hrs.	After two years of health began to eat too fast and too much fruit, failed to observe feces or determine intestinal rate, and had a *recurrence* of both diseases. Weight 158 lbs., feces soft, and intestinal rate 13-48 hrs.
G. N.	46	F.	Arthritis, 10 yrs.	Laxatives +, and cereal foods +	Same, 145 lbs. Formed, 60-134 hrs.	Well, 148 lbs. Normal, 63-111 hrs.	After a year of health, while travelling, ate irregularly and too fast, failed to determine rate or observe feces, and had a *recurrence*. After returning home ate better. Weight 145 lbs., feces formed, and intestinal rate 51-111 hrs.
F. A. R.	65	F.	Arthritis, 8 yrs.	Fast −, fat +, laxatives +	Same, 124 lbs. Soft, 14-87 hrs.	Well, 134 lbs. Normal, 48-110 hrs.	After two years of health in a country home moved to the city and ate out, fast, and too much fruit. She failed to observe feces and determine rate, and had a *recurrence*. Weight 128 lbs., rate 12-70 hrs.
L. N.	25	F.	Psoriasis, 20 yrs.	Fast −, laxatives +, vegetables −	Same, 124 lbs. Soft, 14-87 hrs.	Well, 115 lbs. Formed, 48-110 hrs.	After a year of health ate too fast and too much cereal food, observed *soft feces*, and had rates of 12-62, and 15-87 hrs. Shortly afterward, had a *recurrence*. Weight 107 lbs., rate 13-72 hrs.
W. O. S.	39	M.	Iritis, 6 yrs	Fast −, irregular −, cereals +	Same, 208 lbs. Soft, 15-38 hrs.	Well, 146 lbs. Normal, 43-114 hrs.	After three years of health went off on a vacation and ate too much and too fast, had soft feces and rate of about 17-67 hrs. shortly afterward had a *recurrence*. Weight 144 lbs., rate 36-87 hrs.

Record 2

Health measures to continue: to eat slowly, of a small breakfast and lunch, but a substantial dinner; also eat many vegetables and fruit according to absorption. Then determine rate and weight every few weeks and bring in a complete record of nutrition in January.

	Rate	Weight
Oct. 25	41 to 132 hrs.	132 lbs.
Nov. 8	65 to 134 hrs.	134 lbs.
Nov. 22	65 to 128 hrs.	133 lbs.
Dec. 6	40 to 114 hrs.	134 lbs.
Dec. 21	63 to 130 hrs.	135 lbs.
Jan. 4	62 to 127 hrs.	135 lbs.

Wednesday, January 17, 1935

6:50 to 7:25 p.m., steak, potato, beets, string beans, roll, chocolate pie.

7:30 p.m., seeds taken to mark this meal.

Thursday

7:30 to 7:15 a.m., bran muffins, tea.

9 a.m., normal dejection.

1:05 to 1:25 p.m., beef stew, cracker, apple pie.

6:55 to 7:25 p.m., potato soup, chicken, potato, squash, spinach, rice pudding.

Friday

7:45 to 8 a.m., toast, tea.

9:20 a.m., normal dejection.

1:10 to 1:25 p.m., fish chowder, cracker, apple sauce, cookies.

7 to 7:25 p.m., chicken soup, lamb, potato, parsnips, broccoli, roll, orange sherbert and cake.

10:45 p.m., normal dejection.

Saturday

8 to 8:20 a.m., corn bread, coffee.

9:30 a.m., normal dejection with first seeds; *initial intestinal rate, 62 hrs.*

1 to 1:20 p.m., scrambled eggs, bacon, lima beans, cut up oranges, cake.

7 to 7:25 p.m., oyster stew, sweet breads, potato, cauliflower, brussels sprouts, bread pudding.

Sunday

8:30 to 8:50 a.m., brown bread, coffee.

10:30 a.m., normal dejection with seeds.

1:30 to 1:50 p.m., cheese omelette, vegetable salad, crackers, peach pie.

6:30 to 7 p.m., beef, potato, beets, egg plant, roll, prune whip, cake.

Monday

7:30 to 7:50 a.m., toast, marmalade, tea.

1:05 to 1:20 p.m., lamb stew, bread, baked apple.

3:15 p.m., normal dejection with seeds.

6:45 to 7:15 p.m., beef broth, cod, sweet potato, turnips, celery, roll, Indian pudding.

11 p.m., normal dejection with seeds.

Tuesday

7:35 to 7:50 a.m., wheat muffins, tea.

10:30 a.m., normal dejection with last seeds; *final intestinal rate, 135 hrs.*

1 to 1:25 p.m., fried egg, fried potatoes, roll, mince pie.

6:55 to 7:30 p.m., celery soup, veal, potato, beans, spinach, roll, tapioca.

Wednesday

7:30 to 7:50 a.m., corn muffins, tea.

9:30 a.m., normal dejection without seeds.

1 to 1:15 p.m., veal stew, roll, prunes, cake.

7 to 7:25 p.m., duck, apple sauce, potato, peas, string beans, squash pie.

THE NORMAL NUTRITIVE APPARATUS, THE INTESTINAL RATE AND ASSIMILATION

Through the wisdom of the body as the circuit of the blood is influenced by sleep, rest, food, exercise, affections of the mind, and the like (8), so must the cycle of digestion and absorption be influenced by similar factors. Again as the work and performance of the heart are adapted to the needs of the body (8), so must the work and actions of the nutritive apparatus be adapted to the requirements of the bodily tissues for sustenance. Thus, the nutritive apparatus operates automatically and with reasoning, and these qualities are exhibited in the digestive pouches especially; for proper food in the primary pouch, the stomach, is normally churned to promote mixing, digestion and partial absorption of the aliment, but very unsuitable food excites the vomiting reflex and is rejected to protect the body from the absorption of injurious substances. Similarly, thoroughly comminuted, complete and properly proportioned food in the secondary digestive pouch, the proximal colon, is normally kneaded back and forth to promote complete digestion and absorption, but aliment not fulfilling these requirements is propelled onward rapidly and dejected. Such a propulsive action may seem inconsequential; but Howell writes, "the value of this reversal of movement of the bowels (antiperistalsis) at this particular point would seem to lie in the fact that it delays the passage of material toward the rectum, and by thoroughly mixing it gives increased opportunities for the completion of digestion and absorption" (9).

The sign of the normal operation of the proximal colon is the formation of the intestinal contents into uniform segments, which make up the normal feces; for Elliott and Barclay-Smith write, "a segment from its (the proximal colon) contents is every now and then nipped off by a ring of constriction, and carried away to be moulded in its further passage down the colon to the firm fecal nodule" (10). The passage of the colonic contents in man is brought about by two *different actions; one, evidently* the normal is that of Fischl and Porges (11) by which the contents of the proximal colon are moulded into segments that are passed slowly through the distal colon; the other, evidently the abnormal is that of Holzknecht (12), by which large irregular masses form in the caecum and are passed propulsively through the entire colon. This act procedures soft and formless feces. which in the practice of anabolic nutrition are a sign of intestinal indigestion and malnutrition.

The intestinal rate as another index of absorption in animals, has been shown by Gross (13) to exhibit marked variations according to the kinds of food ingested. In properly fed rats, charcoal takes 9 hours to appear in, and 120 hours to disappear from the feces; but in those without vitamin A the intestinal rate was 6 to 48 hours, and in those without vitamin B it was 16 to 384 hours. This abnormally slow rate is explained by the fact that animals in vitamin B deficiency lose their appetite and consume so little food, that their bodily needs are not fulfilled and at the same time enough passed on to produce normal dejections. The intestinal rate as an index of absorption in man, has been described by Burnett (14) to exhibit similar variations according to the kinds of food ingested and other factors. In adult patients who corrected their ways of eating to operate the proximal colon normally, one and sometimes two segmented stools are common daily, yet the marked evening meal takes about 63 hours to appear in, and 134 hours to disappear from the feces; and this rate is considered normal. On the other hand, in those who eat erroneously, the dejections are often irregular and the rate is frequently 14 to 63 hours. Such a rate is shown in Record 1, and in the practice of anabolic nutrition is applied as a sign of malabsorption, by which there is a failure in the final and most important phase of nutrition—assimilation.

Structural changes in the bone cells of scorbutic animals from a failure of assimilation have been described by Wolbach and Howe (15); for they state that "after seven to nine days of deficient diet there was an increase in the number of osteoblasts applied to the cartilage columns. . . From twelve to sixteen days . . . the osteoblasts migrated from their original positions and assumed the shapes of fibroblasts." Thus, when highly specialized cells do not receive normal nutrient substances from food, they revert to a lower and commoner type of cell. "But the administration of orange juice . . . was promptly followed by the deposition of bone matrix between the fibroblast-like cells." Thus the consumption of complete food and normal assimilation, produced a regeneration of the osteoblasts and the formation of normal bone.

This process appears similar to that produced in patients from malabsorption to cause metabolic diseases; for through a failure of normal nutrient substances to maintain a weak skin, joints, or some other tissue, in a healthy state, the cells break down in a recognized disease. And in these circumstances, the cause of the disease can only be removed by the production of normal nutrient substances to regenerate the cells, and this process is evidently brought about in patients by the correction of erroneous ways of eating and living to operate the nutritive apparatus normally, and to create anabolic or normal nutrition by which an exact and improved state of health can be *acquired and subsequently controlled.*

CONCLUSIONS

Health has been a vague and variable condition of the human body, but its maintenance and restoration have been more assured of late, from an understanding of the needs of the healthy body for complete food; and thus some of the established deficiency diseases have been relieved, cured, and prevented. Obviously eating too fast and too much, irregularly, disproportioned meals, or the frequest use of laxatives are not conducive to normal nutrition and health; but by regarding the digestive system as a perfect nutritive apparatus in which a function of the colon only oper-

ates from right eating to produce normal feces and normal intestinal rates, these erroneous ways of eating provoke a previously unrecognized kind of intestinal indigestion, malnutrition and disease. This is because the food consumed does not complete its cycle of digestion and absorption, and nourishment goes through instead of into the body. Thus, there is a failure in the final and most important phase of the nutritive processes—assimilation—and the exact and improved state of health from anabolic or normal nutrition, cannot be maintained. Principles for the creation and control of this state of health to cure disease, have been applied in the treatment of some of the skin diseases and arthritis; and patients who understood and carried out the principles, have been cured of these diseases.

Studies on Constitution and Ulcer

III. Gastric Secretion in the Healthy Members of "Ulcer Families"*

By

JACOB MEYER, M.D.

P. LEVITSKY

CHICAGO, ILLINOIS

SINCE statistics disclose a high familial incidence of gastric and duodenal ulcer, the existence of an ulcer constitution, which in response to harmful stimuli might lead to this disease has been postulated by various authors (1).

Celsus, at the beginning of the Christian era, wrote that constitution may predispose to certain diseases; and Hunter, in the eighteenth century, discussed how constitution may prevent or facilitate the occurrence of disease (2). Many attempts have been made since then to define constitution, but no definition seems to be generally acceptable.

With respect to ulcer the tendency has consisted largely in an effort to express constitution either anthropometrically as a definite body build, usually asthenic (3), or on a functional basis. The "vagotonia" of Eppinger and Hess (4) and the "vasoneurotic" diathesis of Mueller (5) are illustrations of this thesis which have neither been proven nor accepted (6).

More recently, the concept of "organ diathesis" has been formulated, which tries to explain the tendency to ulcer formation in weakness of individual organs, *i.e.* the proximal gastro-intestinal tract.

Dr. Arthur Hurst (7) originally described the significance of variations in gastric physiology and anatomy occurring in normal, healthy adults. The extremes of these variations have been classified as hypersthenic and as hyposthenic stomachs, the former characterized by hyperchlorhydria, hypersecretion and a high, horizontal, hypertonic, rapidly emptying stomach, and the latter by hypochlorhydria, hyposecretion and an elongated, ptotic, slowly emptying stomach.

Both types of stomach usually are found to be associated with physical types of body build. The hypersthenic stomach with "hypersthenic," muscular, persons, and the hyposthenic stomach with "hyposthenic," slender persons with weak musculature. Both types of stomach are frequently familial, and, according to Hurst, both predispose to the occurrence of peptic ulcer. The hypersthenic individual is distinct from

Submitted April 27, 1936.

the vagotonic, because it lacks the symptoms of bradycardia, hyperidrosis, myosis, etc. The hypersthenic stomach frequently contains free acid in the fasting state. Its tendency to hyperacidity renders it prone to harmful effects of alcohol, smoking, etc. The tendency of the hyposthenic stomach to hypochlorhydria diminishes the bactericidal properties of this organ and

thus, according to Hurst, facilitates the development of a gastritis or duodenitis which may lead to ulcer. The observations of Hurst have, however, been contradicted (8).

It has been our experience, that one or more members of the family of a patient with gastric or duodenal ulcer soon or late developed this disease and therefore our attention was drawn toward these families as potential sources of future gastro-intestinal pathology. It was assumed that the healthy members of these families would have some abnormality in gastric function that might predispose them to the occurrence of ulcer. We therefore undertook a study of the gastric secretion in the normal asymptomatic members of the families of ulcer patients.

METHODS AND PROCEDURE

The present work presents a statistical analysis of gastric secretion in the relatives of ulcer patients. All were healthy, few had slight gastro-intestinal complaints, as anyone may have from time to time, none presented an anamnesis indicating ulcer, and none had consulted a physician for gastro-intestinal complaints. Table I presents the variety of relationship occurring in the series. Forty-one females and 41 males from 54 families, with an age range between 8 and 64 years are represented.

Gastric secretion was obtained by Rehfuss tube. The residue of the fasting stomach was aspirated, measured and titrated. At ten minute intervals, two more aspirations were made, the specimen measured, 10 c.c. retained for titration, and the remainder returned. These latter values represent basal secretion. The test meal was now provided. It consisted of 8 arrowroot cookies and 400 c.c. water (9). After one hour, the stomach was emptied completely, the contents measured, a 10 c.c. specimen retained for titration, and the balance returned. One-half or one hour later, the final aspiration and measurement were made. The results of titration were expressed in clinical units.

The data accumulated in this manner have been statistically analyzed in accordance with the technique presented by Vanzant, Alvarez, Berkson and Eusterman (9). This method made possible a comparison between the present group and the normal standards of secretion accumulated from nearly 4000 subjects. The comparison is expressed as the mean difference in clinical units between the values found and the normal standard, plus or minus the probable error. The cases lacking free acid following the test meal have been calculated separately, the percentage incidence of achlorhydria in each age group being compared with the normal incidence of anacidity for that classification. The values for free and combined acidity used in calculation are those obtained one hour after the test meal. The later aspiration subserved to differentiate between true and apparent achlorhydria. The former indicates the absence of free acid in all three specimens after the test meal, the latter indicates the absence of free acid in the one hour specimen but its appearance one-half or one hour later. Histamine was never employed in order to preserve identity with the experimental conditions of the standards employed.

RESULTS

Table II summarizes the number of subjects, the average volume and the free and total acidity in response to the test meal, the characteristics of the fasting residue, and the incidence of achlorhydria for each age group.

As is evident in Table III*, the healthy members of ulcer families, both male and female, present a distinctly lower free acid response to the stimulus of an Ewald meal than does a normal group. The males further reveal a statistically significant comparative depression in total acidity, and a suggestively significant relative augmentation in volume. The changes in total acidity and volume are not significant among the females.

Achlorhydria is more frequent among females, and no male in the age range of 15-64 years exhibited absence of free acid. However, the percentage incidence of achlorhydria for the female ulcer relatives is actually lower than the normal prevalence of anacidity (9).

Vanzant, *et al*, have not reported the incidence of anacidity below the age of twenty years. However, extrapolation of their data would indicate that the young members of ulcer families demonstrate a high incidence of achlorhydria. Muhl (10) and Klumpp and Neale (11) report no instance of achlorhydria in a total of 120 normal children. Yet Wright found that 4% of 230 children were devoid of free acid (12).

Finally the fasting residue of the ulcer relatives deviates from normal, tending frequently to be of the same degree of acidity as the specimen taken one hour after the test meal (see Table II).

COMMENT

In a general way, the above data demonstrate the existence of significant secretory deviations from normal in the seemingly healthy members of ulcer

*The values for total acidity and volume in Table III do not include the results from the younger groups up to 20 years of age because no comparable statistical material of a normal population of that age group is existing (see 9).

TABLE II

Gastric secretion of normal relatives of ulcer patients

		Residue			Ewald Meal				
								Achlorhydria

families, the male deviations exceeding the female.

Whether or not these variations can be legitimately interpreted as representing a tendency to ulcer formation still remains questionable. In the course of the three years of this study three subjects, asymptomatic at the time of the test, ultimately developed clinically demonstrable ulcers.

The diminished acidity of the relatives of ulcer patients may result, as Hurst supposed, in a lowered antiseptic barrier with ultimate gastritis and ulceration. This theory may explain the pathogenesis of gastritis or of acute ulcers much more than it does that of the chronic ulcer.

Another possibility is that hypoacidity may merely be one of the symptoms of a more fundamental pathology, as yet unknown, which, independent of secretory changes, is capable of inducing ulcer. The presence of rather high acidity in the resting stomach, similar to that of ulcer patients, also points in that direction. If one considers the healthy members of ulcer families as potential ulcer patients, and if one accepts the statistical validity of the hypoacid response to an Ewald meal, of this group, one must assume that the hyperacidity in cases of duodenal ulcer is preceded by hypoacidity, and that hyperacidity may be caused by an unknown factor or by the ulcer and not *vice versa* as is generally believed.

TABLE III

Average difference in gastric secretion between healthy ulcer relatives and normal population

	Males	Females
Free Acidity	— 18.1 ± 1.834	— 9.6 ± 1.686
Total Acidity	— 8.8 ± 2.832	— 5.4 ± 2.610
Volume c.c.	— 7.3 ± 2.617	— 5.3 ± 2.207

It is important to emphasize that the members of ulcer families represent potential ulcer patients, so that if the incidence of ulcer is to be curtailed, in the absence of specific therapy, adequate prophylaxis should be directed toward protection of these vulnerable individuals.

While it is not within the scope of this paper to discuss in detail the prophylaxis of ulcer, our present studies suggests the advisability of such simple precautions as the following: In view of the low acidity which we found to be prevalent in this family group, attention to oral hygiene and the removal of infectious foci should be stressed, as this may prevent bacterial invasion of the stomach and its sequela.

In view of the fact that mental and physical overstress, and particularly social and sexual maladjustments are important as ideological factors in the genesis of the ulcer syndrome, correction of these

should be attempted particularly in the healthy members of ulcer families.

SUMMARY

While it is known that ulcer "runs" in families, nothing has been known about gastric functions of the healthy members of such families, which have to be considered as potential ulcer patients. Therefore, the gastric function was tested in 82 healthy relatives of ulcer patients, not having stomach or intestinal complaints. The response of this group to an Ewald meal revealed too low values for free acidity in both males and females and the presence of much free acid in the resting stomachs of a great number of them. The abnormal response to the Ewald meal and possibly also the high acidity of the resting stomach may be interpreted as predisposing to gastritis. It may be the expression, however, of an abnormal gastric mechanism, so far unknown, which may produce both, abnormal secretion and ulcer. Dietary, hygienic, and social adjustment as prophylaxis for ulcer is advocated among the healthy members of ulcer families.

Note: We gratefully acknowledge the help of our Social Service Department through Miss Eleanor Scher.

Nocturnal and Diurnal Variations in the Acidity of the Spontaneous Secretion of Gastric Juice*

By

FRANCES A. HELLEBRANDT, M.D., RUBYE H. TEPPER, M.S.

HELEN GRANT, M.S.

and

RUTH CATHERWOOD, M.S.

MADISON, WISCONSIN

THE views have been prevalent concerning the secretory activity of the empty stomach. Beaumont (1847) observed that gastric juice was never found free in the unstimulated stomach of Alexis St. Martin, and Pavlov (1910) noted that in the absence of psychic disturbances or food, the gastric glands of the dog likewise remained quiescent. Carlson (1916) subsequently presented evidence in support of a more or less continuous secretion in the absence of food or psychic factors as a normal phenomenon in both animals and man. Divergence of opinion has persisted. Much of the substantiating evidence has been indirect. Rehfuss and Hawk (1921) inferred the character of interdigestive gastric behavior from a study of the fasting residuum aspirated preceding the administration of a test meal. Crohn and Reiss (1917) had already reported that an "after secretion" might persist for many hours post-prandial. They considered it a manifestation of pathological hypersecretion. In a careful series of physiological studies, Lim (1924) looked upon the juice secreted in the absence of all intentional and avoidable stimuli as a "basal secretion" to which the subsequent enhanced activity of the glands as a result of controlled stimulation must be related. It was not until 1926 that Galambos suggested the periodic aspiration of the fasting stomach as a feasible clinical diagnostic method. In 1931 Polland and Bloomfield made a systematic study of this basal secretion and also suggested that herein might lie a new function

test of first importance in the clinical assay of the secretory capacity of the gastric mucosa. The whole problem has been recently reviewed by Babkin (1932). He believes there can be no further denial of the "secretion of a regular gastric juice by fasting man," and advances the view that such secretion is always due to the action of normal or abnormal stimuli, the glands remaining at rest or active according to whether these stimuli are present or absent.

The observations cited have been limited to a relatively few hours of either continuous or periodic aspiration. The only long time studies of the continuous secretion of the fasting stomach are those concerned with the determination of gastric secretory activity during sleep at night. Chalfen (1928), Henning and Norpoth (1932, 1933) and Winkelstein

(1935) report that secretory rest characterizes the nocturnal response of normal subjects in contradistinction to the elaboration of a juice of high acid value by patients suffering from peptic or duodenal ulcer. The object of our study was to extend day time observations to comparable periods and to contrast the diurnal and nocturnal response of the same subject.

METHODS

All observations were made upon young adult university women free from gastric symptoms or disease. Day time studies commenced 15 hours after the last meal. Fluids were forced on the preceding day, to ob-

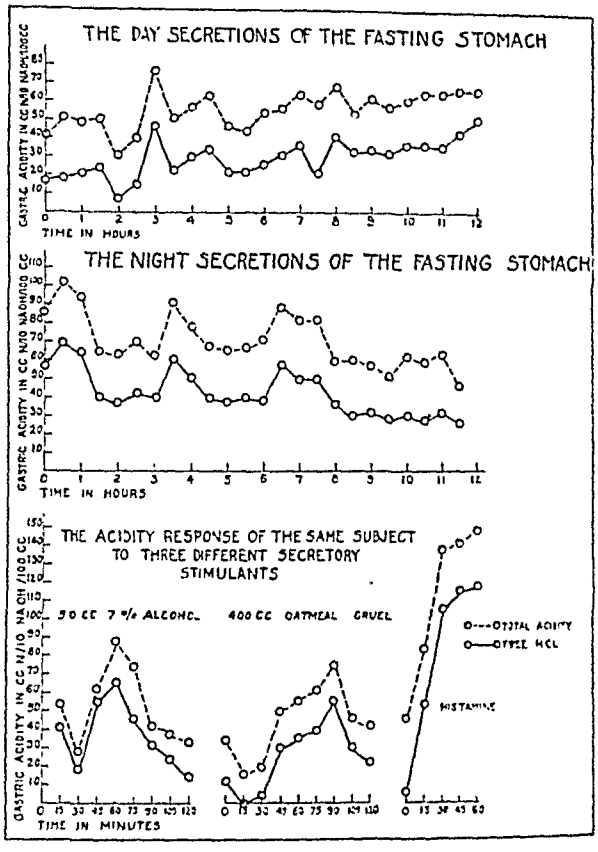

Fig. 1. A comparative study of the acidity of the spontaneous day and night secretion of the fasting stomach of a subject responding well to histamine, .1 mg./10 kilo, and to routine test meals of gruel and alcohol. Note that the scale of times referred to the axis of abscissas in the short experiments is double that of the 12 hour observations.

tain maximal hydration and thus allay the discomfort of abstinence and combat the aspiration of fluids. On the day before nocturnal observations the usual breakfast was eaten, avoiding only meats and fried foods. Luncheon consisted solely of nutritious liquids. Dinner was omitted. Fluids were stopped within three hours of the experiment, since Rehfuss and his coworkers had found that water alone might act as a secretory stimulant (1914).

The technique of intubation was learned prior to the use of any individual as a subject. The Rehfuss tube was modified by attachment of the metal olive to 1 16 by 1 32 or 3 32 by 1/32 Dakin's tubing. This was voluntarily swallowed without artificial lubrication or the ingestion of fluids, and was well tolerated for

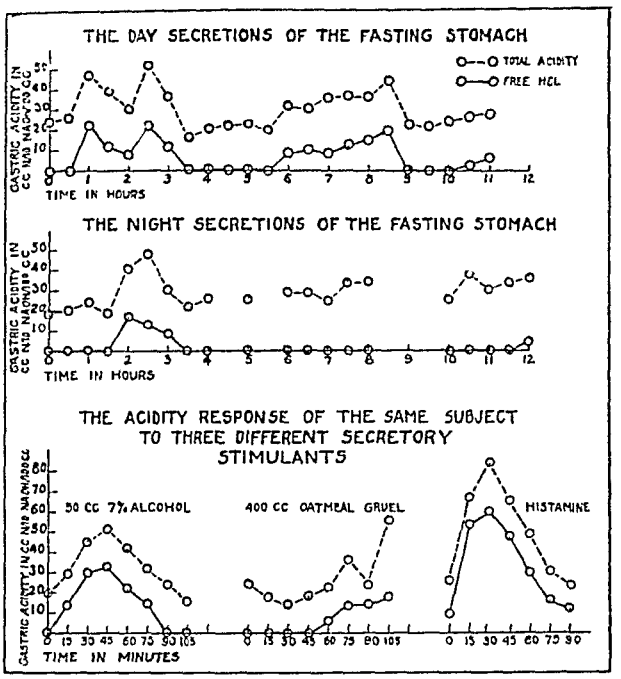

Fig. 2. A comparative study of the acidity of the spontaneous day and night secretion of the fasting stomach of a subject responding poorly to gruel, and only moderately to alcohol and histamine stimulation. The scale of times referred to the axis of abscissas in the short experiments is double that of the 12 hour observations.

many hours. The heavy end of the tube was allowed to seek the lowest pole of the stomach. Before assuming recumbency at night, the correct tube position was determined with the subject in the sitting posture, after which fixation was attained by the application of adhesive plaster. All nocturnal observations were made with the subject sleeping in the laboratory, from 7 to 10 of the night hours being spent in bed. Day time experiments were performed with the subject up and about, occupied with quiet sedentary work. Saliva was not expectorated. A small sample of the gastric contents was aspirated with a syringe half hourly, first mixing the fluid which had accumulated in the stomach. Chemical analyses were performed immediately after the withdrawal of gastric juice, both day and night. Visible mucus was removed by centrifugal separation. The supernatant gastric juice was decanted and free and total acidity were determined by titrating with .1 N NaOH, using a micro burette, fitted as described by Hollander (1931) with a hypodermic needle. During the early experiments Töpfer's reagent and phenolphthalein were used to determine end points for free and total acidity respectively. Subsequently bromphenol blue and phenol red were substituted. The presence of bile was noted and its quantity estimated by subjective evaluation of the color of the freshly drawn sample. Blood was detected by the benzidine test. When positive in repeated aspirations the experiment was terminated.

The procedure is open to criticism because of contamination of the gastric secretion by saliva, pyloric escape of gastric contents, reflux from the duodenum, and the unknown influence of the residue of preceding glandular activity upon the acid value of succeeding samples. To perform a long time experiment under the most ideal conditions the following modification of procedure was adopted in one case. Observations were commenced after a 22 hour fast, to rid the upper alimentary tract of food. The subject remained in a semi-recumbent position in bed during 17 consecutive hours of observation. Saliva was continuously removed by suction. The gastric contents were continuously aspirated by the application of a constant gentle negative pressure, using the intestinal decompression method of Wangensteen (1933). A liter and a half of gastric juice was withdrawn. To combat the dehydration and hypochlorema which accompany the total loss of gastric secretion (Dragstedt and Ellis, 1930) 1400 c.c. of warm physiological saline were introduced by hypodermoclysis between the 6th and 11th hours of observation.

RESULTS

In a series of 55 preliminary experiments on 6 normal young adult women we confirmed the presence of a continuous secretion in the fasting stomach over periods varying from 1 to 6 hours. A total of 34 long time experiments were then performed, 21 during the night and 12 during the day, on 18 and 11 subjects respectively. Seven of the day and 3 of the night ob-

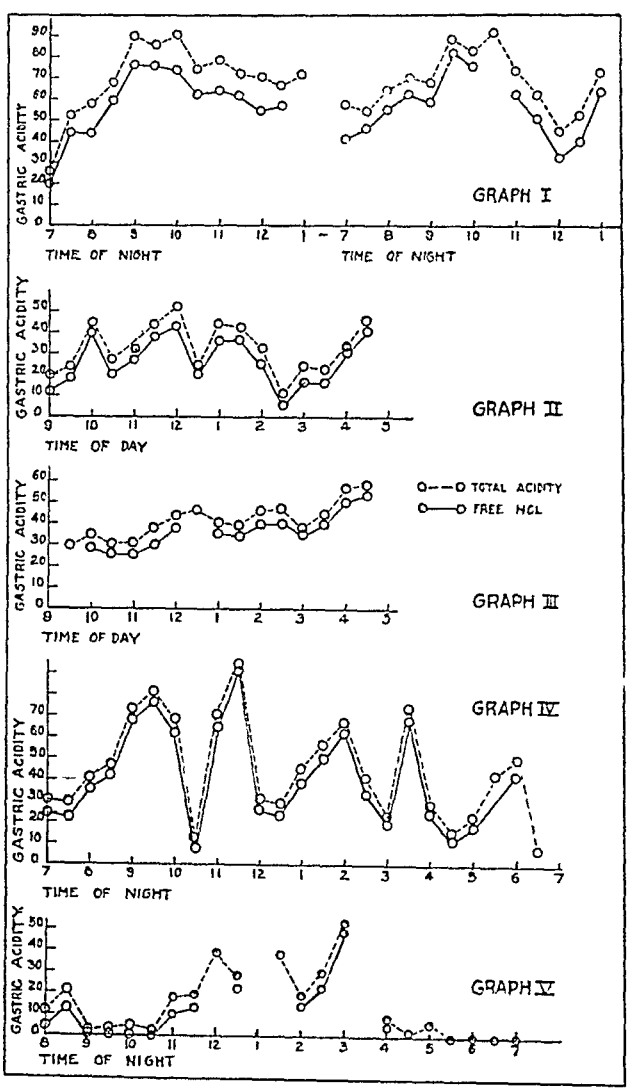

Fig. 3. Illustrative graphic records showing the continuous secretion of the fasting stomach and the periodicity of its acid response in the absence of intentional stimulation.

servations were limited to 8 consecutive hours. The remaining 20 were 12 hours in duration. One extended over 17 hours and thus involved day and night aspiration. Eleven subjects submitted to both diurnal and nocturnal observations.

The juice aspirated was often of high acid value and not infrequently exceeded in acidity that produced in response to a test meal. Figure 1 illustrates the acidity of the gastric juice withdrawn from both the stimulated and spontaneously secreting stomach. The glandular activity of the fasting stomach was sufficiently continuous to yield samples of gastric juice at half hour intervals, day and night. The distinct periodicity in the intensity of the reaction makes the contours of the spontaneous acidity curves indistinguishable from those induced by deliberate stimulation.

The behavior of the empty stomach and the functional capacity of the mucosal acid producing cells as revealed by test meals or histamine stimulation seem to be related. This is evident in the comparison of Figures 1 and 2. So low was the secretory rate in the latter experiments that adequate samples were obtained from the fasting stomach with difficulty and occasionally no juice could be withdrawn. There is a uniformity in the pattern and level of the response, night, day, and after stimulation.

In general, the acidity of the gastric juice spontaneously liberated during sleep at night was *higher* than that produced in the day time. Table I presents the individual average free and total acidity of the night and day secretion of 11 subjects. By arranging these in order of the titration value of the nocturnal free HCl, the mean day secretion exceeds the night in potency only in those cases in which the functional capacity of the mucosa is lowest. If the stomach has the ability to liberate spontaneously a juice of high acid value, its nocturnal responsiveness exceeds that of the day. This is more evident in Table II, in which are presented the single highest day and night free and total acidity values. The mean highest acidities for the group as a whole were 58.8 for free HCl during the night and 73.81 for total acidity, in contrast to 43.8 and 57.8 during the day.

Graph I of Figure 3 shows the similarity of the gastric behavior of one subject on two different nights. The acidity is high and the response is cyclic. The periodic character of the reaction is typically illustrated in Graph II. The greatest suppression of the day in contrast to the night secretion of a single subject, is reproduced in Graph III and IV. This subject slept well and uninterruptedly throughout the major portion of the night, precluding psychic stimulation of external origin. On the contrary the subjects whose acidity response is reproduced in Graph V, slept fitfully and spent a restless and uncomfortable night in the laboratory.

Continuous aspiration of the gastric contents did not affect the appearance of recurrent waves of rising acidity (Figure 4). The findings were identical with those yielded by periodic sampling. The acidity was highest during the night. Toward morning it dropped abruptly until no free HCl was detected in the aspirated gastric contents. Subsequently it rose again. The period of maximal acidity coincided with the interval of saline administration. Fluid lost by gastric aspiration was roughly compensated for by injection, but absorption from the subcutaneous tissues was incomplete when the experiment was terminated 6 hours after the cessation of hypodermoclysis. At the end of 17 hours there was no sign of secretory exhaustion.

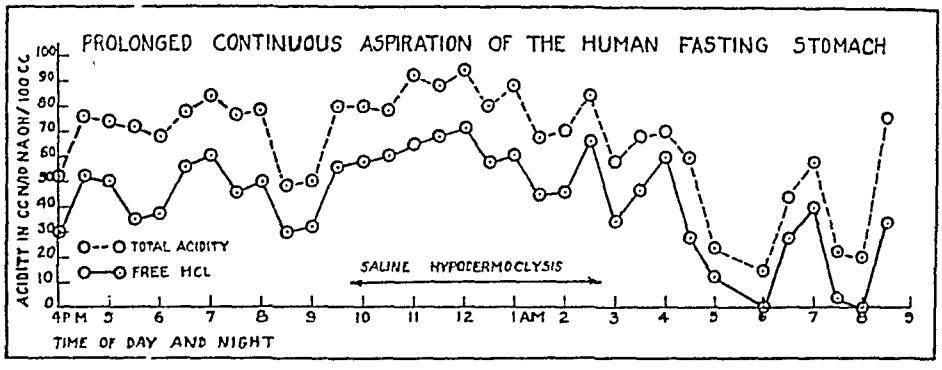

Fig. 4. Nocturnal and diurnal variations in the acidity of the spontaneous secretion of gastric juice, continuously collected for 17 consecutive hours by the decompression method of Wangensteen. Fluid loss was partially compensated by saline hypodemoclysis.

Bile was almost continuously present in the samples withdrawn from the fasting stomach. Regurgitation as evidenced by fluctuations in the intensity of the color of the aspirated samples was inconstantly related to depressions in acidity. When the secretion rate was low the benzidine test was most frequently positive for occult blood. We had already called attention to the difficulty of obtaining blood free samples from the fasting stomach on double intubation (Hellebrandt, 1935). It suggests that the metal olive of the Rehfuss tube may traumatize the mucosa when unbuffered by a fluid test meal, especially during vigorous peristalsis. The use of a thin, weighted, perforated rubber tube did not completely abolish this finding. Trauma by intubation aspiration may be more common than is supposed. This negates the value of aspiration of the fasting stomach as a practical clinical test. Except for transitory discomfort, our subjects showed no ill effects from the procedure. Milk was administered immediately after the withdrawal of the

tube, and a bland, easily digestible meal was served before discharge from laboratory.

DISCUSSION

If the parietal cells put out a juice of constant acidity and this is elaborated continuously, we can ascribe the spontaneous variations in the titration values of aspirated samples to several mechanisms. There is ample opportunity for contamination with extra-gastric secretions, of which we have partially eliminated only saliva as a contributory acidity depressant. In the absence of quantitative data it is impossible to evaluate the importance of duodenal regurgitation. The purest gastric juice is a mixture of the secretions of a variety of cells, susceptible to selective stimulation and unequal activity (Hollander, 1931; Vinsberg and Babkin, 1931). Carlson (1916) had suggested that the stimulus for the continuous secretion of the empty stomach may reside in the autodigestion of constituents normally present in the gastric juice. Continuous aspiration affords minimal opportunity for stimulation by this route, yet periodicity in the level of the response remains as evident as that characteristic of a stomach from which small samples of the contents are only intermittently removed. That the mechanism is a humoral one emanating from the intestine seems improbable. It would be difficult to explain the cyclic nature of its release.

Chalfen (1928) suggested that the secretion of the fasting stomach was a conditioned reflex, since in his experience the exclusion of psychic stimuli by sleep was associated with a secretory depression. This is not in agreement with our findings. Further, the day oscillations in our experiments display no peak acidities coincident with the habitual time of eating. Henning and Norpoth (1932) also considered the fasting secretion a psychoreflex. Like Chalfen, they find the abolition of secretion characteristic of sleep. In their experiments, the "waking state" was associated with a prompt elevation in the acid level of the juice aspirated from the stomach. Inability to sleep comfortably under laboratory conditions was never accompanied by the production of a juice of high acid value in our experiments. The maximal acidities were obtained from subjects whose sleep was least affected by the unavoidable disturbances incidental to the procedure.

The largest series of normal subjects showing low or absent free HCl during sleep at night is that of Winkelstein (1935). However, aspirations were commenced by him only 2½ hours after a full dinner, and although food fragments were present for 4 hours thereafter, the quantity of secretion was small, "seldom exceeding 15 c.c. in the whole night," and 40 per cent of the normal subjects showed no free HCl. Babkin (1932) had reported that food residues, even when present in insignificant amounts, exert a stimulating effect on the secretion of gastric juice. Digestion must have been at its height when Winkelstein's experiments were commenced. Carlson (1915) estimated that 700 c.c. of gastric juice were produced by a normal man in response to an average meal. In our long time experiment, the mucosa elaborated a juice of high average acidity at a mean rate of 14.7 c.c. 10 min. for 17 consecutive hours without evidence of secretory exhaustion. It is difficult to reconcile these observations with the findings of Winkelstein.

Carlson (1916) demonstrated that gastric hunger contractions are augmented during sleep. Subsequently (1923) referring to the heightened secretion observed by Luckhardt and Johnston (1924) in hypnotic sleep, he predicted that an augmentation of gastric gland activity would probably also be found to occur during natural sleep at night, the secretory and motor mechanisms of the stomach being similarly governed. Our findings substantiate this prediction. Gastric secretion, like gastric motility, is augmented during sleep at night. Both are characterized by irregularly recurrent periods of activity and relative quiescence. We have already postulated a secretory-motor relationship in the fasting stomach of man (Hellebrandt, 1935), acidity and motility varying in unison. The demonstration of fluctuations in the acidity of the fasting secretion, day and night, adds weight to this hypothesis.

CONCLUSIONS

1. The normal fasting stomach secretes continuously, day and night.

2. The fasting gastric contents may exceed in acidity that accumulated in response to test meal stimulation.

3. The acidity of the fasting secretion rises and falls intermittently, in the absence of all intentional stimulation.

4. The mean acidity of the night secretion of the fasting stomach exceeds that of the day secretion.

5. A secretory-motor relationship is postulated to explain the fluctuation of the acid values of the aspirated gastric contents though there is no quantitative evidence to exclude extra-gastric contamination as the modus operandi.

On the Inhibitory Effect of Corpus Luteum on Gastric Secretion*

By

IRA A. MANVILLE, M.D., Ph.D.

and

WALTER R. MUNROE, B.S.

PORTLAND, OREGON

IT has been noticed in this laboratory that pregnant bitches do not respond normally to secretion and histamine stimulation of gastric secretory activity. Strauss and Castle (1, 2) have presented evidence showing that pregnant women usually show a tendency toward achlorhydria. The possibility that one of the hormones elaborated in the ovary during pregnancy exerts this inhibitory effect was investigated.

METHODS

Pinky, the animal used in this work, is a young healthy adult male dog who had an ileo-gastrostomy performed in November, 1935. He is normal in all other respects. Before each experiment food was withheld for 12 to 36 hours. The dog was trained to lie quietly during the experiment. Through the fistula, a rubber tube was introduced on the end of which was a light rubber balloon. The other end of the tube was connected to a chloroform manometer whose float recorded pressure variations on a smoked drum. A catheter with the closed end perforated by a number of openings was also inserted through the fistula. The outer end of the catheter was kept closed with a clamp between operations. At five minute intervals the clamp was removed, the gastric contents aspirated and 50 c.c. of tap water were introduced. Ten c.c. portions of the aspirated gastric content were titrated with N/40 NaOH to determine free and total acid. Töpfer's reagent and phenolphthalien were used as indicators. The titration values of the gastric contents gave information about the relative amount of secretion (at least of hydrochloric acid) during the five minute period the sample was in the stomach.

EXPERIMENTAL

Control experiments were run using 2 mg. pilocarpine HCl as a stimulant. This resulted in a greatly increased flow of gastric juice with a high acidity and a high mucus content. Peptic activity was not determined. The results of a typical experiment are shown in Table I.

We feel that the course of gastric secretion may be followed best by the free acid values because of the buffering effect exerted by the varying amounts of saliva and mucus in the various samples. Results of a typical experiment using pilocarpine HCl show that the maximum acidity is reached about 37 minutes after stimulation, although high values are reached within 25 minutes and are maintained for at least 40 minutes.

After control experiments were done the animal was put on a course of corpus luteum (Lilly). It was given one ampoule a day (each ampoule represents 3 grains dessicated corpus luteum) for 13 days. At the end of this time the effect of pilocarpine was again determined. The animal was given 2 mg. pilocarpine HCl accompanied by 1 c.c. corpus luteum. Results of this experiment are given under Experiment I in the Table. The acid values in this experiment did not rise so high as in the control experiment. One hour and four minutes after stimulation, the acidity began to increase. This experiment seems to show some inhibition of pilocarpine stimulation by corpus luteum. As the effect of corpus luteum in this experiment seemed to be slight, another experiment was performed, the animal being given 2 mg. pilocarpine accompanied by 2 c.c. of corpus luteum, followed in one-half hour by another 2 c.c. dose. The results of this experiment are given in Experiment II in the Table. This experiment shows no inhibition by corpus luteum of the secretion induced by pilocarpine. Corpus luteum also apparently had no effect upon the gastric motility. In the second experiment, the peak of acidity was reached 48 minutes after stimulation and the acid values were of the same order as those obtained when pilocarpine alone was given. High acid values were still present when the experiment was discontinued one hour after pilocarpine stimulation.

TABLE I

Time	Control Free Ac.	Control Total Ac.	Experiment I Free Ac.	Experiment I Total Ac.	Experiment II Free Ac.	Experiment II Total Ac.

70			4.5	6.0		

Free and total acid values are expressed as c.c. N/40 HCl.
In Experiment I, 2 mg. pilocarpine and 1 c.c. corpus luteum were given.
In Experiment II, 2 mg. pilocarpine and 2 c.c. corpus luteum were given followed by 2 c.c. corpus luteum one-half hour later.
Time is expressed in minutes from pilocarpine stimulation. 00 minutes is the time the pilocarpine was given.

DISCUSSION

Strauss and Castle state that the greatest decline in gastric acidity occurs during the second trimester of pregnancy with a rise during the last month to the level observed in the third month. As the corpus luteum involutes about the start of the eighth month of pregnancy, it was thought that perhaps the corpus luteum hormone might be the responsible agent. The doses of corpus luteum used in these experiments were probably physiologically adequate.

Since corpus luteum, in the dosage used, has no power of inhibiting the gastric secretory response to pilocarpine and since the animal produced acid just as efficiently after the course of corpus luteum as before, we conclude that the corpus luteum used does not contain the agent responsible for the diminished gastric acidity of pregnancy.

SECTION III—*Nutrition*

Experimental Gout in Turkeys*

By

JESSE L. BOLLMAN, M.D.

and

CARL F. SCHLOTTHAUER, D.V.M.

ROCHESTER, MINNESOTA

THE major portion of the uric acid excreted by birds is derived from the conversion of urea in ordinary protein metabolism. Administration of urea increases the excretion of uric acid by normal birds. Minkowski demonstrated that the synthesis of uric acid from urea occurred in the livers of birds since such synthesis did not occur if birds were hepatectomized. Von Mach (2), after repeating these experiments, pointed out that uric acid did not entirely disappear from the urine of hepatectomized birds owing to the two sources of uric acid in these animals, one by synthesis from urea, which process occurs only in the liver, and the other from the purine bases liberated by nuclear metabolism throughout the body; the latter is independent of the action of the liver.

Urea is not converted to uric acid by animals other than birds and reptiles. Other animals, including man, possess a mechanism for the destruction of uric acid which varies in efficiency in the various species. The liver is also responsible for the destruction of uric acid (3). The normal dog excretes only traces of uric acid, but after removal of the liver large amounts of uric acid are found in the urine and no evidence of destruction of uric acid can be demonstrated. Because of the ability of animals to destroy uric acid this substance does not increase beyond a certain level in the blood of animals with complete urinary retention.

Urinary retention by birds produces a rapid, marked increase in the uric acid content of the blood and little elevation of the concentration of blood urea. Uremia is indicated by high levels of uric acid in the blood; values from 150 to 400 mg. per cent have been obtained (4). Under these circumstances there occurs a deposition of white, crystalline urates on all of the visceral surfaces and on the fascia of the muscles; deposits are also found on the articular surfaces of the joints (5, 6). The term "visceral gout" often has been applied to this condition and probably has led to some confusion in the literature. Until there is proof that uremia and tophaceous gout of birds are similar conditions we feel that the term "gout" should be reserved for the condition characterized by definite tophi.

Spontaneous avian gout is not infrequent among captive birds of zoölogical gardens. According to Fox (7), it occurs most often among parrots, gallinaceous and accipitrine birds, and herons. It has also been reported to have occurred among domestic birds such as the chicken, duck, goose and turkey. Kaupp (8) observed gout in a flock of capons. Kionka (9) experimentally produced gout in hens which he maintained exclusively on a diet of fat-free horse flesh. Gout became apparent in periods of from three to fifteen months. The symptoms and physical characteristics of this disease were similar to those of spontaneously occurring gout.

METHODS

One set of experiments was begun January 10, 1934, with eighteen turkeys which were at that time seven months old. They were placed, two each, in nine pens. Four pens were small cages measuring 26 by 26 inches, within an unheated building, and the remaining five pens were outside runs affording ample opportunity for exercise and a slightly greater range of temperature. Five combinations of diet were fed to these turkeys. The birds in outside pens and inside cages, which received identical paired diets, had free access to their food at all times. All turkeys received a basic diet of a commercial turkey mash containing wheat bran, middlings, yellow corn meal, meat and bone scraps, ground barley, soybean oil meal, ground oats, alfalfa meal, dried skimmed milk, dried buttermilk, limestone, salt, and cod liver oil. This diet contained 20 per cent protein, 4 per cent fat and 45 per cent carbohydrate. The five diets used were as follows: (1) the turkey mash without any additions, (2) turkey mash mixed with equal quantities of ground raw horse flesh, (3) turkey mash mixed with 5 per cent of crystalline urea, (4) turkey mash with a few leaves of fresh green spinach, and (5) turkey mash and cracker meal in equal quantities. Two birds were changed to diet 2 after having had diet 1 for eighteen weeks, and one bird was changed to diet 1 after having had diet 3 for twenty-six weeks.

All turkeys were weighed at approximately the same hour each week. At this time we also procured 1 c.c. of blood from the wing vein of each turkey. Determinations of the blood uric acid were made after proper dilutions, by the method of Folin (10).

On October 2, 1934, twenty other turkeys were placed in outside runs and given a diet composed of equal parts of turkey mash and ground raw horse meat. Four birds of the twenty were given intramuscular injections, three times each week, of 1 c.c. of a solution of uranium acetate containing 25 mg. of uranium. Four other birds of the twenty similarly received injections of solution of lead acetate containing 10 mg. of lead. Still four other birds of the twenty were fed cinchophen mixed with the food so

* Division of Experimental Medicine, The Mayo Foundation.
Submitted April 22, 1936.

that each turkey of the four received approximately 1 gm. of cinchophen each day.

Necropsy was performed on each of the thirty-eight birds; some died during the course of the experiments, but most survived the entire period. No pathologic changes were found in the visceral organs of any birds except those found associated with enterohepatitis. The lesions that were considered as gout consisted of tophaceous nodules about the feet, knees, or wings, and the depositions of chalky white material in the articular surfaces of the joints of the extremities. In examination of most of the gouty birds all of these changes were found, but in examination of a few the joints of the feet only were involved. Microscopic examination of the material from the gouty deposits revealed numerous needle-like crystals.

RESULTS

The results of these experiments were summarized in Tables I and II from which most of the pertinent data can be ascertained. Comparisons of the values for the blood uric acid of the birds as determined in the different weeks disclosed variations such as are indicated in Tables I and II. However, many of the low values for uric acid, determined on the blood of birds in which the concentration of uric acid usually was found to be high, were obtained at times when the animals were sick. Some turkeys had enterohepatitis and others were not disposed to eat well at times when gouty tophi were actively developing.

The effect of feeding and of fasting on the blood uric acid of birds which did not have gout (Table III) indicates that the blood uric acid rises after a meal and that the amount of the rise is dependent on the nature of the diet. Much greater rises were obtained when diets contained an increased amount of protein or of urea. If the animal was then fasted, the blood uric acid decreased rapidly so that low values were obtained within twenty-four hours. During the next twenty-four hours there appeared to be a slight rise in the uric acid content of the blood. Similar changes were observed in animals with gouty tophi both in the active stage and in quiescent periods. The blood uric acid of gouty birds after a fast of twenty-four hours appeared to be slightly higher than that of normal birds but the values were small when compared to those usually found in examination of the blood of turkeys that had access to food. The blood uric acid of fasting gouty turkeys was found to be between 3.0 and 5.0 mg. per cent, while that of normal turkeys was between 1.5 and 4.0 mg. per cent.

If the turkeys were allowed free access to food, little difference was found in the uric acid content of the blood whether their exercise was or was not restricted by confinement in cages. The restricted animals did take less food, probably because the cages were in a building which reduced the hours of daylight so that these birds roosted longer than their outdoor neighbors. The concentration of uric acid in their blood, however, was not significantly different from that found in the outdoor birds which received the corresponding diet.

The uric acid content of the blood of the turkeys fed the diet of turkey mash only (Table I) varied but over a period of time was found to be remarkably consistent. Those to whose mash green leaves were added were found to have slightly less uric acid in the blood.

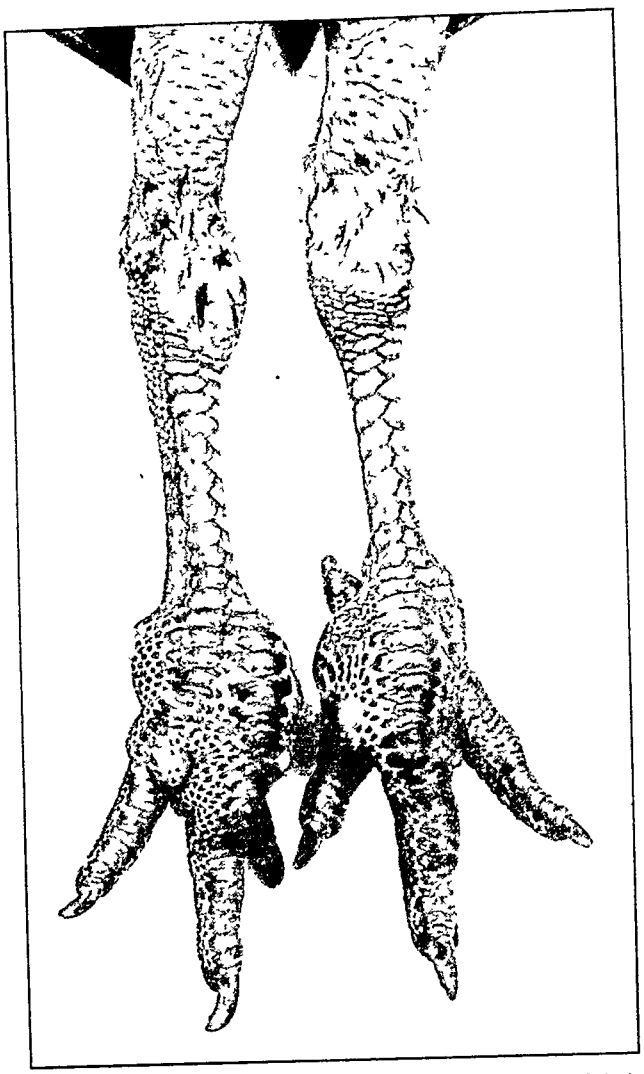

Fig. 1. Gouty feet of turkey which received a diet rich in protein, and injections of uranium (number 13, Table III).

but it is doubtful that any significance should be attached to this small difference. The blood of those birds whose food (cracker meal and turkey mash) contained less protein and more carbohydrate than was contained in the diet of mash and green leaves similarly contained a relatively small amount of uric acid. The addition of urea to the diet apparently increased the uric acid content of the blood above that which would be anticipated with the same diet less the added urea. Greater increases in uric acid were observed in the blood of birds fed the diet containing equal parts of turkey mash and horse flesh. A much wider range of variation in the value for uric acid in the blood was found among those birds which received diets which gave high values for uric acid in the blood.

The administration of cinchophen to birds which were receiving the diet of turkey mash and horse flesh was without effect on the uric acid of the blood. The values found were similar to those that had been obtained when the same bird had been given the same diet without cinchophen; the values also were similar to those obtained when other birds were given the same diet, without addition of cinchophen. The incidence of tophaceous gout and the course of the disease were likewise similar when birds were given this diet, whether or not cinchophen was added.

In the blood of birds that received uranium, values for uric acid were high. Similar results were obtained with the birds that received injections of lead. In the blood of most of the birds which received injections of uranium or lead the concentration of uric acid was higher than might have been anticipated when birds were given the particular protein rich diet employed in the experiment concerned. It should be noted that in the blood of about a third of the birds given uranium or lead the elevation of uric acid was about the same as in that of birds which were given the protein-rich diet only. Therefore, we feel that too much significance should not be placed on the effects of lead or uranium under the conditions of this experiment. Histologic examination of the kidneys of the birds that received lead or uranium disclosed very little abnormality. Only an occasional necrotic tubular cell, with some deposition of calcium could be found; these changes might be attributed to the action of either uranium or lead on the kidneys. Repeated examina-

	38	21.1	35.4	14.4	12	+++

tions of the blood gave no evidence of changes attributable to these poisons.

Lesions of gout developed in nineteen turkeys of the group of twenty-six which received the diet especially rich in protein and in one of the four birds which received urea. No gout developed in any of the eleven birds which received the turkey mash alone or in those which received cracker meal or green leaves in addition to the mash. In all of the birds in which gout developed the value for the blood uric acid was 16 mg. per cent or more for the week or two preceding the appearance of lesions sufficiently characteristic to be considered definitely those of gout. A decrease in the amount of uric acid in the blood frequently occurred during the week or two after gout was apparent. At this time the birds usually took much less food than previously and later the blood uric acid increased when the animals regained their normal appetites. Subsequent loss of wellbeing occurred at times when new tophi appeared to be developing but the presence of old tophi seemed to produce no symptoms.

COMMENT

The first symptom of gout displayed by the affected birds was lameness and difficulty in arising after sitting prone. In the early stages the turkeys spent most of the day prone on the ground, in a manner that made it appear that pain was present or was at least associated with movement. The attacks of pain seemed intermittent, as the birds would move normally again after a few days and then several days later would resume their characteristic positions. Within a few days after the appearance of symptoms, small tophi usually could be observed on the feet. These tophi gradually enlarged, but the enlargement itself seemed to bear no relation to the symptoms observed. Some birds appeared to have pain when the tophi were enlarging but others had no symptoms accompanying the enlargement. We did not observe any material decrease

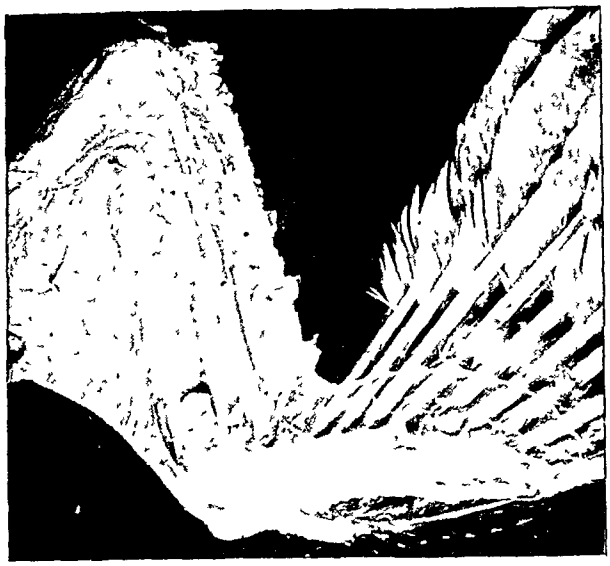

Fig. 3. Gouty tophi in wing of turkey which received a diet rich in protein, and injections of lead (number 17, Table III).

in the size of the large tophi, but small ones disappeared from time to time. Alteration of the diet, with subsequent reduction in the uric acid content of the blood, did not cause rapid diminution in the size of the tophi; although some of the tophi did disappear under these circumstances, others however, were unaltered.

The tophi and articular cavities contained masses of white, semisolid or paste-like material. Microscopic examination of this material disclosed masses of needle-like crystals, frequently arranged in sheaves. Examination of the tophi also revealed these crystals enclosed in connective tissue of varying density. The uric acid content of the pasty material, either from tophi or from the articular cavities, was found to be from 4 to 5 per cent of the moist weight of the material and from 20 to 30 per cent of its dry weight.

From the results obtained it is obvious that the uric acid content of the blood of turkeys under ordinary feeding conditions depends on the protein or the nitrogen content of the diet. The elevation of uric acid is probably not associated with the metabolism of nucleic acid since such elevation also occurred in the blood of birds which were fed urea. It appears probable that the major portion of the uric acid of the blood represents that which has been formed by the liver from urea, either that administered or that formed from the catabolism of protein. This is of course a special mechanism for the formation of uric acid in birds and reptiles and is not present in mammals.

Fig. 4. Gouty involvement of the tibiometatarsal joint of turkeys (numbers 18 and 19, Table III).

In some previous experiments (11) we observed that the yolks of eggs from our gouty birds were almost white, but that other birds of the same flock produced eggs with yellow yolks. In these experiments the addition of green spinach leaves to the diet produced eggs with yellow yolks but the level of uric acid in the blood was not reduced more than when carbohydrate was added to the diet. It seems probable that the gouty birds in our former experiments did not pick up green plants from their pen as did those not affected.

We have used eight female turkeys to one male in these experiments, so that our number of male turkeys is not sufficient to warrant conclusions as to the sex incidence of gout under these conditions. We could find no difference, on the basis of sex, in the amount of uric acid in the blood of birds which were receiving the same diet. Two of the birds in which gout developed were males and we saw no indication of resistance to gout in either sex. It appeared that gout developed after the value for the uric acid of the blood had remained at 16 mg. per cent or higher for several days. Severe cold weather might have precipitated some attacks of gout. Several birds had symptoms and tophi developed in them immediately following exposure to severe cold weather, after they had failed to have symptoms for several weeks when the value for the uric acid in their blood was in the neighborhood of 16 mg. per cent. In many other birds, however, gout developed without exposure to cold.

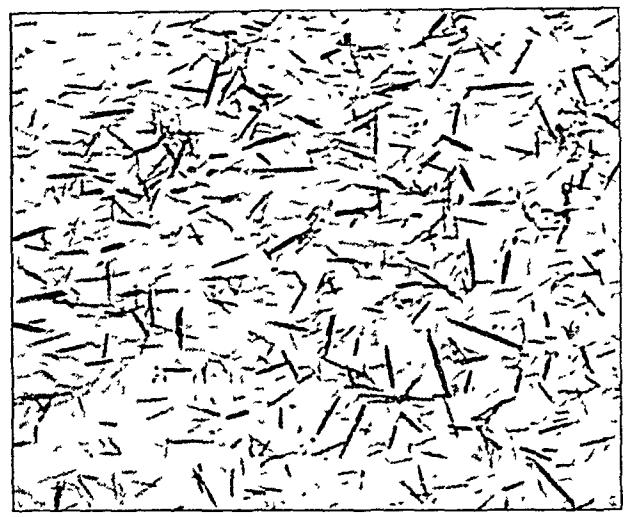

Fig. 5. Crystals of urates expressed from gouty tophus of turkey (x750).

SUMMARY

The blood uric acid of turkeys is elevated after feeding and is diminished to a low level after fasting. When free access to food is allowed the value for the uric acid in the blood is usually found to be several times that for the fasting bird. The level of the blood uric acid is greatly increased by additions of protein or of urea to the diet.

Symptoms of gout and the development of gouty

tophi on the extremities and gouty depositions in the articular cavities occur in turkeys if the uric acid in the blood is maintained at a high level for several days.

Administration of cinhcophen appeared to have no effect on the uric acid content of the blood or on the cccurrence or symptoms of gout in those animals in which gout was present.

Administration of nephrotoxic agents (uranium and lead) appeared to increase the uric acid content of the blood slightly and to hasten the appearance of gout.

Spontaneous Hyperinsulinism Due to Pancreatic Adenoma in a Patient with Carcinoma of the Sigmoid -- a Catastrophic Conjunction*

By

CHARLES-FRANCIS LONG, M.D.

L. SHEPLIN, M.D.

and

D. B. FISHBACK, M.D.

PHILADELPHIA, PENNSYLVANIA

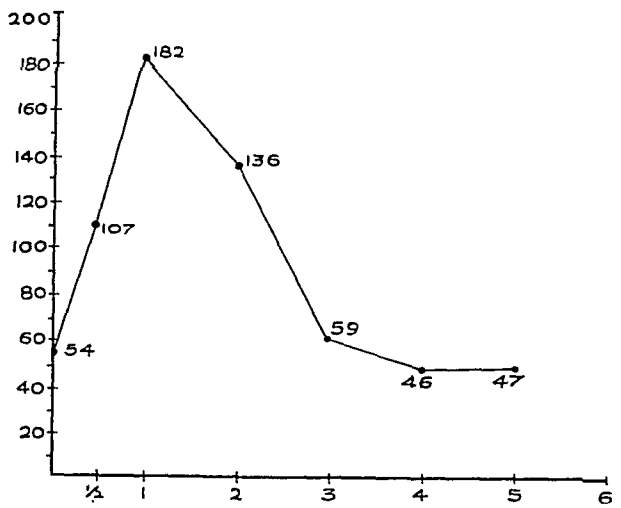
SPONTANEOUS hyperinsulinism might be called the "isomer" of diabetes. In diabetes a lack of endogenous insulin results in hyperglycemia. The mirror condition entails an excessive secretion of endogenous insulin with varying degrees of hypoglycemic shock. Clinical types of hyperinsulinism have been well defined by Seale Harris (1), who points out that more cases are not recognized because physicians fail to watch for them. However, the general symptoms are familiar enough in the ordinary case and need not be further reported in the literature.

The instance here reported showed two independent lesions in a single patient: one benign, causing devastating symptoms; the other malignant with very few symptoms; both conspired to produce death.

The significance of the history in leading to the diagnosis can only be appreciated if one remembers that orthodox Jewish custom requires a fast for twenty-four hours on the Day of Atonement.

History: On October 27, 1935, a white male, age 45, was sent by Dr. H. Fine to the service of Dr. Edwin Heller with the chief complaint of "spells" and hemorrhoids. On first examination the following facts were determined concerning him:

Being a pious man, it had been his custom to spend the Day of Atonement (Yom Kippur) in synagogue fasting. On this holiday preceding his admission, his wife came to synagogue about eleven o'clock in the morning and found him in a kind of walking stupor. He did not recognize her; he did not respond intelligently to questions; he seemed to be "out on his feet." He was taken to a physician's office but on the way was made to drink a cup of coffee so that within half an hour after arriving at the doctor's office he was perfectly rational. At five o'clock on the morning of his admission his wife was awakened by his heavy breathing and found him unconscious. He did not regain consciousness for two and one-half to three hours.



This story aroused the suspicion of what later proved to be the true diagnosis, and the patient was deliberately asked concerning his eating habits and his sensations when

Fig. 1. Low power microphotograph showing enlarged islands of Langerhans within the adenoma.

*From the Medical Wards and Laboratories of the Jewish Hospital. Submitted May 29, 1936.

required to go without food beyond the usual mealtime. His answer was that for many years hunger had always forced him to eat immediately because failure to do so would cause severe pain in his stomach and a sense of weakness. The patient was a mentally alert, obese, white male of apparently 45 to 50. There was no abnormal physical finding except the hemorrhoids. The *diagnosis of spontaneous hyperinsulinism* was made at this examination clinically. Two nights later he became suddenly unconscious. A specimen of blood was obtained before treatment was instituted. Its sugar content was 30 mgm. per 100 c.c. The Resident reported that 10 c.c. of 50% glucose intravenously brought the man back to complete consciousness even before the injection was finished. The blood sugar curve on a six hour observation is as follows and seems identical with those reported in many cases by Dr. Seale Harris:

Graph 1. Five hour glucose tolerance test. Ordinate shows blood sugar in milligrams per hundred c.c. Abscissa shows time interval in hours. The test had to be terminated at the fifth hour due to symptoms of oncoming shock.

Diagnostic discussion: Having established the fact of hyperinsulinism, our next quest was its cause (2, 3).

1. Was it the pituitary? No, for the X-ray Department reported a normal *sella turcica.*

2. Was it deficient liver glycogen? No, for with a fasting blood sugar of 68 mgs., one c.c. of adrenalin by hypodermic raised the blood sugar to 100 mgs. within half an hour without feeding any sugar.

3. Was it interference with the regulating center, *i.e.,* over-activity of the parasympathetics? No, for the pulse remained normal, the pupils normal, and the eye grounds showed no evidence of intracranial pressure.

Thus, we were forced to conclude, by eliminating other factors to the best of our ability, that intrinsic over-activity of the insular pancreatic tissue (adenoma) was basic in this patient's symptoms (4).

The patient's hemorrhoids had been bothering him for several years but only recently began to bleed, and seemed to us at first not a very significant part of the history. With X-ray and proctoscopic help we investigated further and found that the underlying condition was a polypoid cancer low in the sigmoid, for which we advised surgery. After a few days spent arranging his personal affairs, the patient returned to Dr. Frank Block's surgical service for operation. He had a stormy but complete convalescence from his first stage surgical episode. Dr. Block was asked to palpate the pancreas in an effort to discover an adenoma but reported that none could be felt. Later developments certainly corroborated this report for it was only by dint of thorough search that the lesion was finally discovered at the autopsy. Forty-eight hours after the second stage surgical procedure the patient suddenly collapsed and died.

Fig. 2. High power microphotograph from edge of islands shown in Fig. 1, demonstrating the exclusively insulinogenic type of cell present.

The *diagnosis of sigmoid adeno-carcinoma* gave credence to the possibility of pancreatic metastasis. We felt that, theoretically at least, such a metastasis should *decrease* rather than *increase* insulinogenic activity. Consequently, our *clinical diagnosis* at death was: "Adeno-carcinoma of the sigmoid with probable pancreatic adenoma."

AUTOPSY (D.B.F.)

At autopsy the pancreas was smaller than normal, being about half the size one would expect in a patient of this man's weight. With the fat removed it was remarkably thin and flat and in its tail there was a firm gray nodule the size of a pea. The histo-pathologic study of this nodule proved it to be an adenoma involving the islands of Langerhans. No carcinoma cells were present. The histo-pathology of the head of the pancreas indicated a marked interstitial fibrosis but no adenomatous tissue was discovered in this location.

It was found that all malignant tissue in the bowel had been removed. The pelvic peritoneum was walled off with easily broken adhesions. The parietal peritoneum was reddened with roughly 100 c.c. of blood-tinged fluid incarcerated here.

The rest of the autopsy was negative.

SUMMARY

We report a case of spontaneous hyperinsulinism due to pancreatic adenoma, coexistent with a carcinoma of the recto-sigmoid. The presence of these separate entities was recognized before operation and they were proved at autopsy.

Enzymic Efficiency in Avitaminosis

III. Influence of Vitamin B_1 and G Deficiencies on the Concentration of Blood and Tissue Enzymes*†

By

M. C. KIK, Ph.D., BARNETT SURE, Ph.D.

and

KATHRYN SUE BUCHANAN, M.S.

With the technical assistance of

JAMES DeWITT, B.S.

FAYETTEVILLE, ARKANSAS

IN previous publications we reported that in vitamin B_1 deficiency there is a reduction in the concentration of pancreatic lipase and esterase (1) but that this avitaminosis produces no demonstrable changes in the proteolytic enzymes trypsin and erepsin (2).

We have since extended our observations to other enzymes and other deficiency diseases. The additional enzymes studied are: pancreatic amylase; hepatic lipase and esterase; blood serum esterase, amylase and phosphatase; also kidney phosphatase in vitamin B_1 deficiency and in a few groups in a deficiency of the vitamin B complex.

In this communication results are submitted on vitamin B_1 and G deficiencies; also on a deficiency of the vitamin B complex. This work is grouped in order to determine whether there is any correlation between enzyme changes and the deficiency of several factors of the B group and uncomplicated vitamin B deficiency.

Throughout this study the experiments were carried out in pairs, using litter mates of the same sex and restricting the control to the same plane of nutrition as the avitaminotic animals.

METHODS OF PROCEDURE

The technique for the titration of the various enzymes was the same as recently employed in investigations of Enzymic Changes in Malignancy (3).

The criterion for B_1 deficiency was extent of loss of weight. In addition to 18 to 20 groups used in this study, polyneuritis was produced in the majority of 30 groups of animals on the ration of Ammerman and Waterman (4). As a vitamin B_1 supplement for the control animals graduated doses of a concentrate furnished by the Eli Lilly Research Laboratories were used. The controls for the polyneuritic rats received daily 10 γ of Merck's crystalline vitamin B_1.

In the G experiment's a daily allowance of 20 to 40 γ of crystalline B_1, supplementing a diet deficient in the vitamin B complex, proved a successful procedure for the production of dermatitis. The term G includes what the English workers at present recognize as flavin plus B_6 (5).

There were approximately 4,000 titrations carried out in this investigation. It is, therefore, impossible to submit detailed data. Furthermore, since the changes in enzyme concentration are not, with a few exceptions, proportional to loss of weight expressed in per cent of body weight or to the severity of the polyneuritis or dermatitis, all the results have been averaged and summarized which are presented in Tables I to III.

In the compilation of the tabular data it was considered important to show not only the per cent of increase or decrease in enzyme concentration of the pathologic animals compared with their litter mate controls, but also to indicate the per cent of the groups of animals which showed the particular change.

VITAMIN B_1 DEFICIENCY

Influence of the Extent of Loss of Body Weight and Polyneuritis on the Concentration of Blood and Tissue Enzymes: The animals were 40 to 55 days of age and weighed 110 to 150 gm. The losses of weight ranged from 4 to 47 expressed as per cent of the body weight. The results are quite fluctuating among individual animals; but, on the whole, there is no correlation between extent of loss of body weight and enzyme concentration either in the blood or in the tissues. Neither does the degree of polyneuritis exert any effect on concentration of blood serum and tissue enzymes. From an analysis of Table I it is apparent that there is a marked decrease of pancreatic esterase and an appreciable decrease in the concentration of pancreatic and hepatic lipase. Why the albino rat should be less efficient in the digestive efficiency of esters than true fats, the esters being simpler substances than fats, is difficult to explain.

Polyneuritis associated with only small losses of body weight shows no noteworthy changes in enzyme concentration. The small changes in the concentration of blood serum esterase in vitamin B_1 deficiency is in accordance with the results reported by Green (6).

VITAMIN G DEFICIENCY

The majority of the groups of animals for this study were one and one-half to two months old and weighed 95 to 110 gm. There were also a number of groups selected from older stock, four to five months old, and weighing 150 to 210 gm. The losses of weight ranged from 2 to 35 per cent of the body weight. Sixty per cent of the pathologic animals developed dermatitis. Neither extent of loss of weight nor severity of dermatitis had any noteworthy influence on concentration of blood or tissue enzymes.

An examination of Table II shows a 20.9 per cent decrease in the concentration of blood serum phosphatase. We have no explanation for these results in view of the fact that in a deficiency of the vitamin B complex there is an average 26.3 per cent increase in the concentration of this blood serum enzyme (Table

III) and a small increase in this constituent in vitamin B_1 deficiency.

DEFICIENCY OF VITAMIN B COMPLEX

This investigation was carried out with two groups of animals of different ages. One group was four to six weeks old and weighed 65 to 85 gm. and the other two to five months old and weighed 130 to 200 gm. The losses of weight ranged from 7 to 34 per cent of the body weight.

The appreciable increase in the concentration of the blood serum phosphatase may be correlated with pathologic changes in osteogenetic tissues found in this avitaminosis (7), since blood serum phosphatase is high in bony disorders (8). We would like to state, however, in this connection, that work in progress indicates that, unlike the experience of investigators in human rickets (9), we are finding very little increase in concentration of blood serum phosphatase in experimental rickets, which is in harmony with the recent observations of Scoz (10).

There is also an appreciable decrease in hepatic lipase in a deficiency of the vitamin B complex. Although we previously found no change in ereptic activity in vitamin B_1 deficiency, 60 per cent of the groups in vitamin B complex deficiency show a 27.7 per cent increase, the significance of which is also not clear.

SUMMARY

1. Summarizing the results of this investigation, there is no noteworthy change in the digestive efficiency of either the proteolytic or the amylolytic enzymes in vitamins B or G deficiency, or in a deficiency of the vitamin B complex.

2. There is a marked decrease in the digestive efficiency of pancreatic esterase and a moderate decrease in the concentration of pancreatic and hepatic lipase in vitamin B_1 deficiency, suggesting a disturbance in digestion of fats in this avitaminosis.

3. An appreciable increase was observed in concentration of blood serum phosphatase in a deficiency of the vitamin B complex.

4. With the exception of a 20 per cent decrease in the concentration of blood serum phosphatase, no noteworthy changes in concentration of blood or tissue enzymes were found in vitamin G deficiency.

Enzymic Efficiency in Avitaminosis

IV. Influence of Vitamin A Deficiency on Concentration of Blood and Tissue Enzymes.*†

By

BARNETT SURE, Ph.D., M. C. KIK, Ph.D.

and

KATHRYN SUE BUCHANAN, M.S.

With the technical assistance of

JAMES DeWITT, B.S.

FAYETTEVILLE, ARKANSAS

VITAMIN A deficiency was produced on a dietary regime previously outlined (1). The same biological procedure of paired feeding, using litter mates of the same sex and controlling the plane of nutrition as employed previously (2) was adopted in this investigation. The animals were two to four months old when started on the experiments and weighed from 112 to 176 gm. Large animals were selected, in order to have the opportunity to observe various stages of this avitaminosis by lengthening the depletion and experimental periods. Various stages of vitamin A deficiency were encountered, i.e., prolonged maintenance to large losses of weight; the persistence of the cornified vaginal epithelium in the females; incipient ophthalmin to severe eye lesions; and various combinations of such symptoms. The losses of body weight ranged from 1 to 42 per cent.

There was a total of 1832 titrations carried out in this study, all of which results were averaged and summarized in Table I, since extent of losses of weight and severity of eye lesions had no specific influence on enzyme concentration either in blood or tissues.

Table I reveals two outstanding facts: the marked reduction in blood serum esterase and the large increase in hepatic lipase. Our results on the blood serum esterase are in agreement with the work of Green (3). While the increase in hepatic lipase occurred only in 47.9 per cent of the pathologic animals, almost an equal proportion of decreases having taken place, the increases that did occur were of a high magnitude—in some cases they were as much as 500 per cent greater than in the litter mate controls on the same plane of nutrition. The large increases in the concentration of liver lipase were found mainly in animals that showed either prolonged maintenance of body weight or early symptoms of vitamin A deficiency. Some of these pathologic animals showed no other symptom than a cornified stage of the vaginal epithelium. Great care was taken in the preparation of the liver tissue for extraction of enzyme with 25 per cent glycerol. It was first washed in distilled water, the blood squeezed out by making a small incision in the organ and then dried on filter paper. The differences in titrations which were of a range of several hundred per cent among pathologic animals of different groups could not be due to varying amounts of blood present in the livers, particularly, since we found only traces of lipase in the blood.

If the animal organism has the capacity to transform esterases into lipases, one might argue that the disappearance of blood serum esterase and the simultaneous accumulation of hepatic lipase is due to the former enzyme being changed to the latter. Since, however, the increases of hepatic lipase in the cases that showed several hundred per cent increase are entirely out of proportion to the decreases in blood serum esterase, it is hardly probable that this mechanism is in operation.

In the presentation of the results of our enzyme studies in avitaminosis completed to date, it is of the greatest interest to present the facts, the significance of some of which may become clear in later years. It is at least encouraging that certain enzyme studies in disease are being successfully applied clinically. For instance, recent enzyme studies (4) indicate a reduced concentration of blood serum enzymes in victims of food allergy, which according to the investigators account for their being unable to split the foreign proteins into amino acids. The foreign proteins then enter the various tissues and produce irritation, hence the allergic reaction. Such victims seem to respond favorably to commercial pancreatic preparations which stimulate the production of the blood enzymes.

The significance of the marked decrease of blood serum esterase in vitamin A deficiency, while not apparent at present, may become clear later when a study of vitamin A pathology is approached from another angle.

An appreciable reduction in hepatic esterase is also apparent from Table I. Whether hepatic esterase is transformed into hepatic lipase is also only a suggestion which requires proof.

Although it has been generally believed that in vitamin deficiency diseases there is a great loss of digestive efficiency, the results of our work to date disclose only a mild disturbance in the digestion of fats in one avitaminosis, namely, vitamin B_1 deficiency. Since the American diet is composed largely of highly milled cereals and is not sufficiently supplemented with fresh fruits, vegetables, and dairy products, it is possible that a large proportion of the population of this country is not only on the border line of vitamin requirements, but is also not receiving the optimum intake of certain mineral elements. Sherman, for instance, emphasizes the deficiency of calcium in the American diet (5), which is an indication of the in-

sufficient consumption of milk which provides the factor of safety in so far as calcium is concerned. What influence avitaminosis would exert on enzymic efficiency when handicapped by deficiency of mineral elements, as it apparently exists in the American diet, deserves investigation. It is possible, however, that there is a deficiency of peptic activity in avitaminosis. Our next efforts then will be directed in this field.

SUMMARY

In vitamin A deficiency there is a marked decrease in the concentration of blood serum esterase, an appreciable decrease in hepatic esterase, and a marked increase in hepatic lipase.

SECTION IV—*Roentgenology*

Roentgenographic Studies of the Mucous Membrane of the Colon
II. Colitis

By

FRANZ J. LUST, M.D.
NEW YORK, NEW YORK

NOT long ago Alvarez wrote (1): "In nine out of ten cases of colitis we cannot find the remotest sign of inflammation in the bowel, the colon looks perfectly normal. The patient is constipated and there was never any diarrhea."

This is an interesting commentary on our knowledge of colitis. We have to depend for the most part on clinical observations for its diagnosis. Pain, gas, change in frequency of bowel movements (constipation or diarrhea) and change in the consistency of the stools with pathological findings (presence of mucus, blood and bacteria) are the commonest findings.

It is well known that depending upon the activity of the process only some of these symptoms need be present. Different authors have endeavored to show

Submitted June 12, 1936.

Fig. 1. A. Simple chronic colitis. Tape-like formation of the mucosa. (Case 1).

changes of the intestines by roentgenographic examination. The routine method shows only those changes which are connected with deformities in the contours of the bowel. Therefore, any method which gives us more information should be welcomed. We have used the "surface technique" in studying colitis, a technique which we described in a previous paper (2).

Surface studies (mucosal) in colitis formerly were performed only rarely. As we outlined in a former presentation (2) the inner surface of the colon is not flat but has folds, and its pliability permits many different changes in appearance. Knothe (3) believes that the different changes found in simple colitis and ulcerative colitis represents various stages of the same disease. We do not feel warranted in taking such a definite stand because the clinical syndrome and the roentgenographic findings are in our opinion too strikingly diverse to represent the same disease.

Chaoul (4) claims that there are no definite roentgenographic findings in simple colitis, that hypertonicity of the colon appears to be the main reason why it is difficult to obtain good roentgenograms. In ulcerative colitis, he finds massive infiltration of the wall of the gut, "stripes" and "marble like" patterns of the mucosa visible through the gas content of the bowel.

Lups (5) in his excellent paper uses different methods: he shows cases examined by the double contrast enema method and also specimens of surface technique roentgenograms in cases in which later autopsies were obtained. He points out, that slight serration, seen after the complete filling method, was not caused by any pathologic process, which could be shown at autopsy. His findings might have been caused by fecal matter which very often adheres firmly to the colon wall in spite of several cleansing enemas, as Fineman and Snyder have shown in their exhibit of 1934 at the Graduate Fortnight of the New York Academy of Medicine. These difficulties must be taken into consideration in any attempt to appraise changes of the mucosal surface of the colon. The important factor therefore in a study of the colon is the appearance of the single mucosal fold as well as of the entire mucosal pattern of the bowel wall.

To date, in the diagnosis of colitis undue stress has been laid upon spasm. We consider spasm to be only a secondary sign. Spasm may be due to the following causes: (1) those entirely extrinsic to the colon, such as ulcer of the stomach or the duodenum, cholecystitis, inflammatory lesions or calculi of the gall bladder or in genito-urinary tract; (2) every organic change in the colon wall produces spasm as in the lesions of colitis, tuberculosis or tumor; (3) every irritation from the content of the gut may have a similar effect; (4) the contrast enema itself, hard fecal matter, gas and parasites need only to be mentioned. As a like effect may be due to so many different causes, one must conclude that spasm can be utilized diagnostically, only as a secondary sign, the importance of which is that its manifestations often are the chief and only cause of discomfort to the patient. A "spastic colon" may be painful and treatment may relieve much of the discomfort. But so far as roentgen diagnosis is concerned spasm has lost its former significance. It would seem, therefore, that a study of the mucosal aspect of the colon now is more valuable, provided certain carefully considered, standard points of the

Fig. 1. B. Simple chronic colitis Appearance of the same case after routine barium enema. (Case 1).

Fig. 2. Nodular hyperplastic colitis. Case 2.

interpretation are recognized and become established.

"Colitis" is such a complex subject that we shall not attempt to cover the field in this communication. Here we shall attempt to present merely our observations on the mucosal changes which we have found in certain instances. We are well aware that many unusual findings of the colon mucosa demand explanation.

CASE REPORTS

(1) Simple chronic colitis. Case 1. The patient, a female, 61 years old, for several years experienced "nervous" diarrhea. In the past few months, she developed constipation alternating with diarrhea. She complained of pain in the left upper abdominal quadrant, gas and rumbling sensations in the left flank. Mucus was observed in the stools, but blood never was observed. Her condition could only be controlled by a restricted diet. The diagnosis was simple chronic colitis.

Fig 1B shows the colon completely filled with barium. No definite pathology is observed. Fig. 1A shows the mucous membrane of the same segment of the colon. One observes that this section of the gut exhibits no haustration. The colon still retains transverse folds, but these folds are shortened and are reduced to the average width of the intestine. The *pattern of the surface* has changed to the form of an uneven mosaic. The single fold has very well defined borders but the pattern is different from the normal The contraction of the colon after evacuation is different from that of the normal. The lumen remains free. The complete filling demonstrates that the gut is not a rigid tube, for its distention after barium enema is normal. Only its power of contraction has become impaired so that it resembles an old rubber hose, which has lost its elasticity. These findings indicate the loss of elasticity of the colon particularly with respect to its contractible functions.

Case 2 (courtesy of the Gouverneur Hospital) demonstrates the mucosal pattern *(Fig. 2)* of a patient affected with colitis for the past ten years. He experiences diarrhea alternating with constipation but never had he noticed mucus or blood in the stools. The patient was on a restricted diet, but continued to have pains in the left lower abdominal quadrant.

Fig. 3 (Case 3). Ulcerative colitis, early stage.

Fig. 4. (Case 4). Ulcerative colitis. Complete filling. No detail visible.

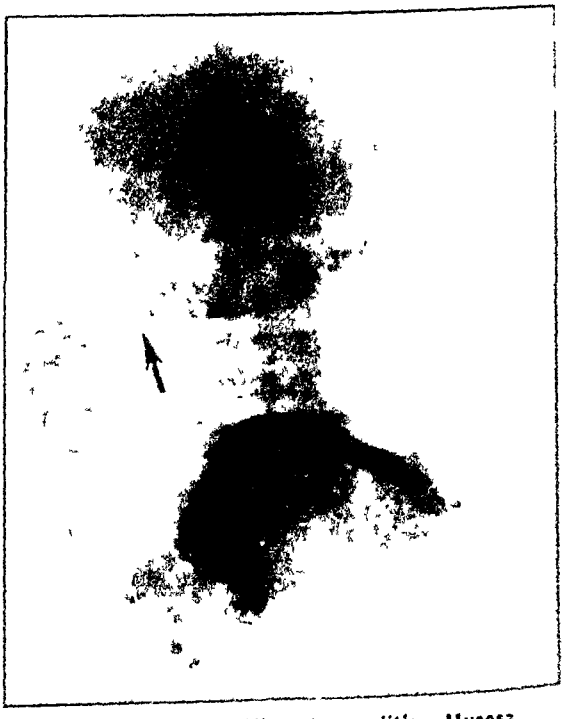

Fig. 5. (Case 4). Ulcerative colitis. Mucosa.

Fig. 6. Ulcerative colitis. (Case 5). Completely filled colon.

Physical examination revealed a palpable and tender sigmoid At the time of the roentgen examination of the colon the patient felt fairly well but recently had been rather constipated The mucosal roentgenogram shows a nodular appearance of the sigmoid, shortening of the rugae and absence of transverse rugae. The appearance of the mucosa may be likened to a well worn and uneven

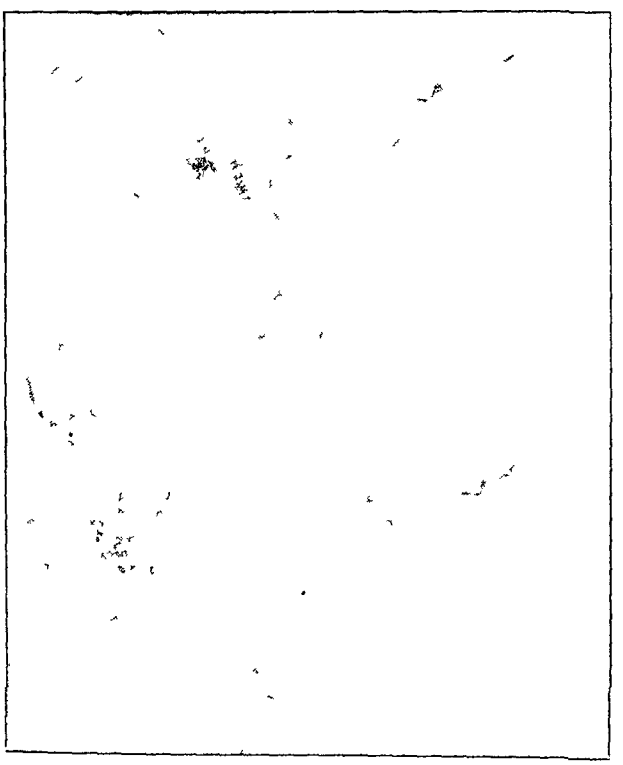

Fig. 7. Ulcerative colitis (Case 5). Mucosa.

Fig 8. Detail of the transversum of Fig. 7. (Case 5).

cobble-stone pavement. The irregular elevations are not quite so distinct as in a true case of polyposis. This nodular hyperplastic type of mucosa probably is a late stage of a chronic, simple colitis.

(2) Ulcerative colitis. Case 3 The patient clinically had an ulcerative colitis of short duration The diagnosis was established by proctoscopy. Blood was present in the stools.

The X-ray examination, after opaque enema, revealed no gross pathology. The post-evacuation roentgenogram *(Fig. 3)* revealed granular changes of the rugae, which otherwise were normal. In an adjacent haustrum one can observe an irregular mucosal surface showing absence of normal mucosal folds, but it will be noted that the haustrum is not impaired; longitudinal rugae connecting the haustrae are present The patient progressed through a short, uneventful recovery from this attack.

Case 4. (Through the courtesy of Dr. H. G. Jacobi) shows the colon of the patient, who was ill for about two weeks. He had blood and mucus in the stools. He suffered from diarrhea and pain in the abdomen. There was tenderness in the right side of the abdomen.

The colon after an opaque enema did not reveal any pathology *(Fig 4)*. The mucosal roentgenogram *(Fig. 5)* indicated that the right segment of the transverse colon

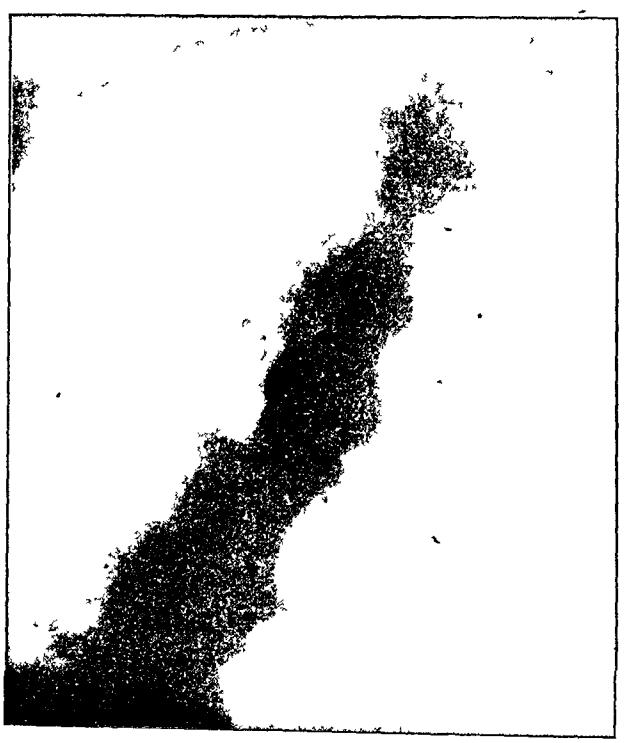

Fig. 9. Detail of the descendens of Fig 7. (Case 5). Ulcerative colitis.

had a dotted, marble-like surface pattern, such as has been described by Chaoul. Otherwise the transverse colon had a normal "barbed-wire" appearance.

This is an instance of localized colon ulceration at a relatively early stage. The patient recovered from this attack in about ten days after his Roentgen study.

Case 5. (Through the courtesy of Dr. A. Bassler). A patient, approximately aged 60, was ill for several years. He had blood and mucus in his stools and had experienced very frequent attacks of diarrhea for the past four months. The question of neoplasm arose because of the patients general condition.

Fig. 6 shows the completely filled colon. This is normal except for several diverticula located in the sigmoid segment. The mucosal studies *(Fig. 7)* however reveal widespread surface pathology. Every part of the colon suggests abnormal patterns, with the exception of the cecum of the ascending colon; these are normal. The transverse colon exhibits a blurred pattern, due to broad, cushion-like swollen rugae *(Fig. 8)*. Transverse rugae are still present. The descending colon *(Fig. 9)* reveals an irregular, undermined surface with small fistulae extending into the deeper layers of its wall. The changes in this segment are similar to those which Knothe (3) described. The anomalies are not due to spasm but to actual pathology of the mucosa and the adjacent mural layers. The sigmoid exhibits diverticula with broad swollen mucosa between them. This is an instance of an advanced, chronic colon ulceration in association with diverticulosis.

DISCUSSION

In this roentgen study of the mucosal anomalies present in colitis this special technique was employed in such cases, which did not exhibit pathology when the barium enema or the progress films alone were employed, but when clinically colon disease seemed to exist. After the colon had been coated with a thin layer of opaque substance, we were able to demonstrate various abnormal mucosal patterns, which suggested localized or general surface lesions or which indicated that, in spite of clinical symptoms, such did not exist.

In simple chronic colitis the mucosa shows changes of nearly all of its folds. The transverse rugae are shortened, they are no longer so distinct as normally. The longitudinal rugae between the transverse rugae disappear. The mucosa has a ribbon like character. The crevasses are not deep, so that in the early cases the colon shows only very faint traces of contrast substance between the folds. In colitis of very long standing but accompanied only by mild symptoms, we were able to demonstrate a nodular, hyperplastic type of mucosa. Probably this is the final stage of the affection.

In ulcerative colitis we observed various types of mucosal change. We were able to demonstrate in one of our patients the different stages of the disease in different segments of the same colon. Early in ulcerative colitis, the general mucosal pattern grossly is unchanged and shows only granular changes on the surface of some of the rugae; later on, a marble-like pattern develops. In severe and chronic ulcerative colitis, the rugae become broad and swollen, or the surface becomes entirely irregular. Small fistulae penetrating into the deeper layers of the gut may be present; these represent undermining of the mucosa. It is interesting to note that unless the ailment is far advanced, the transverse rugae always are present. This is an entirely different observation from the picture exhibited in the mucosal pattern in simple colitis.

In instances of simple colitis, we noted a marked loss of tonicity of the bowel. The lumen was wide open but the haustration had disappeared. The colon lost part of its elasticity. Distension was still possible as proved when it was filled by the barium enema. However, the capacity for normal contraction definitely was impaired. In simple colitis the colon was never observed as rigid or hose-like. However, in ulcerative colitis, impairment of the elasticity was not shown to be present in the early stages; however it is less evident in the late stages of the disease; indeed in advanced instances, the entire colon wall becomes hardened by inflammatory disease; in the healing from such areas of extensive fibrosis may wholly supplant normal mucosal structures and leave a firm rigid, nonfunctioning gut, with or without local areas of stenosis. No mucosa is present in such circumstances, since no trans-mucosal pattern can be shown.

We believe that such observations as we have carried out may improve our understanding of certain clinical symptoms in all forms of colitis. We trust that more extensively this new roentgen technique (so tremendously elaborated by French, Danish and Scandanavian workers) will become more general in this country, so that by comparative roentgen studies, backed by clinical observations and above all, by laparatomy or autopsy records, more reliable interpretative data than now is possible, will be available. It is highly desirable that clinicians better may be able to correlate clinical symptoms and signs, and the results of physical and laboratory examinations with roentgen studies—particularly such studies as are planned deliberately to reveal possible mucosal anomalies.

CONCLUSIONS

1. Roentgenographic studies of the mucosal aspect of the colon in colitis may reveal definite anomalies.

2. These abnormalities are more or less distinctive in simple chronic colitis and in ulcerative colitis, to one familiar with their interpretation.

3. The elasticity of the colon wall would appear to be impaired in simple chronic colitis. In patients with such affections, the colon may become dilated and may exhibit areas incapable of contracting in the normal fashion.

4. Study of the degree and rate of contractibility of the colon may permit an appreciation of why clinically, the subject may quickly experience constipation or diarrhea.

SECTION VII—*Surgery of the Lower Colon and Rectum*

A New Sigmoid Cannula*

By

Z. BERCOVITZ, M.D.†
NEW YORK, NEW YORK

THE object of this report is to describe a new sigmoid cannula which has been useful for aspirating mucus and for washing the bowel mucosa with tepid normal saline through the sigmoidoscope. The mucus and washings, thus obtained, have been used particularly for the identification of amebae, and generally for culture of the bacterial flora and cytological examination of the bowel exudates.

The cannula, (Fig. 1), constructed of nickel silver, is 16.25 inches long and has a uniform bore of 0.064 inches. The outside diameter is 0.100 inches. The proximal 2.5 inches of the cannula is bent at an angle of approximately 135 degrees so that the examining hand is thrown out of the line of vision, thus making it possible to inspect the bowel wall through the sigmoidoscope. A Luer lock at one end permits the attachment of a standard Luer syringe for aspirating mucus or washings. The terminal end of the cannula is dilated into a bulb having a diameter of 0.233 inches. This metallic ball acts as a guide and prevents possible perforation of the bowel wall.

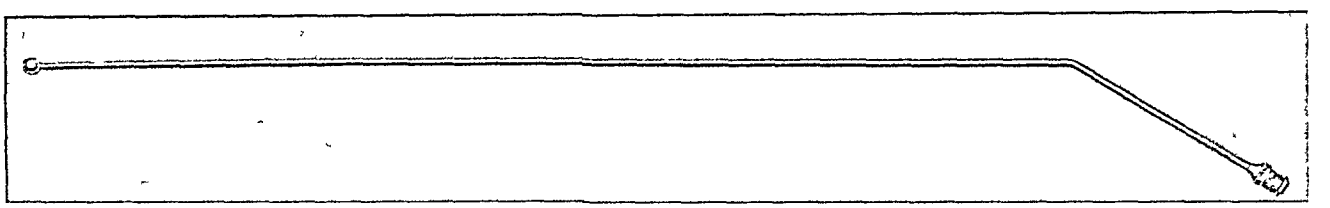

Fig. 1. Author's new sigmoid cannula.

Sigmoidoscopy is done one and one-half hours to two hours after the colonic irrigation or saline enemas. This allows sufficient time for any congestion due to the irrigation to subside and for any mucus higher up in the bowel to come down and be available for aspiration.

Following the passage of the sigmoidoscope to the region of the internal sphincter, the mucosa of that area is observed. At no time should it be necessary to use force in order to pass the sigmoidoscope. If areas showing definite pathology appear in the field of vision, the instrument should not be passed any further than that point. Any spasm is suggestive of underlying pathology and that region should be carefully scrutinized. If the patient has been prepared properly, a satisfactory examination can be made of the bowel mucosa below the area of spasm. If mucus appears in the field of vision, this should be aspirated through the cannula.

An important procedure is to irrigate the congested, edematous and ulcerated mucosa with tepid normal saline through the cannula. The saline wash is aspirated and set aside in a tepid bath for examination. The advantage of irrigating the bowel wall is that all the ulcers even those microscopic in size and regions infested but not yet broken down yield amebae and bacteria which are carried down in the saline suspension. As compared with attempted swabbing this has distinctive advantage in that the amebae are in warm saline suspension, free from the cotton of the applicator. The fields contain only cellular material and amebae. The motility of the amebae is unimpaired, thus making accurate diagnosis possible. In case of marked spasm, irrigation of the bowel wall with tepid normal saline has caused sufficient relaxation to allow easy passage of the sigmoidoscope with a minimum discomfort to the patient. Inflamed areas appear less congested following irrigation with normal saline.

The best results were obtained when specimens were *examined immediately after being secured*, since amebae tend to show degenerative changes rather early and disappear in about half an hour. When examined immediately after aspiration motile forms of amebae are found. Fresh unstained smears of mucus in saline should be examined as well as smears stained in iodine in order to differentiate any suspicious cells. Preparations fixed in Schaudinn's fluid and stained with iron-hematoxylin (Heidenhain's technic) are es-

The author wishes to thank the American Cystoscope Makers, Inc., New York, N. Y., for their cooperation in the development of this instrument.

†Physician in charge, Parasitology Service, Department of Health, City of New York.

Submitted June 3, 1936.

sential in order to confirm the diagnosis and to serve as permanent records of the cases.

The study of mucus specimens gave negative results in all patients in whom the clinical symptoms were not suggestive of amebiasis and in whom sigmoidscopic examination revealed a normal bowel mucosa. As yet, no false positive results have been obtained.

CONCLUSIONS

1. A new cannula for aspirating mucus through the sigmoidoscope has been described.
2. An accurate diagnosis of amebiasis can be made by a study of mucus obtained from the bowel by aspiration with the sigmoid cannula through the sigmoidoscope.
3. Negative results were obtained in all patients whose clinical symptoms were not suggestive of amebiasis and in whom sigmoidoscopic examination revealed normal bowel mucosae. To date, no false positive results have been obtained.
4. The advantages of the procedure outlined are (a) a positive diagnosis can be made within a single day with the minimum expense and inconvenience to the patient, and (b) by means of this technic, the amebae are obtained directly from their place of origin, suspended in warm saline, thus allowing for free motility.
5. The advantages of this instrument are that it is cheap, light, easily handled, does not obstruct the view during sigmoidoscopy and makes it possible to get a specimen that could not otherwise be obtained.

Annual Abstracts of Proctologic Literature

(May, 1934-May, 1935) By CLEMENT L. MARTIN, M.D., Chicago, Illinois

The complete bibliography from which these Abstracts were made will be published in full in the Transactions of the American Proctologic Society, 1935.

NEOPLASMS

The relation of polyps to rectal cancer continues to be investigated. The most careful and worthy work in the last year with which I am familiar is that of *H. Westhues*. His book, "The Pathologico-anatomical Basis of Surgery for Rectal Carcinoma" is reviewed in the December issue of the American Journal of Digestive Diseases and Nutrition. Although I do not fully agree with his classification of polyps, his material is different from my own and his findings are supported by much data.

Bargen and Dixon report on uncommon tumors in the large intestine. They found reported in the literature fibroma, fibromyoma, fibromyxoma, fibromyxangioma, adenofibromyoma, fibroleiomyoma, myoma, adenomyoma, angioma, lipoma, cholesteotoma, paraffinoma, taratoma, glioma, dermoids, and cysts. They report a case of fibroma in the cecum and one of myosarcoma of the rectum. They advise surgical treatment in all these conditions.

Coccyxgeal dermoids are discussed by *Ferrari and Meyer-Burgdorff*. *Fletcher, Woltman and Adson* present a study of sacrococcygeal chordomas.

In his paper on rectal polyps *David* makes the points that a biopsy specimen from the base of the tumor is necessary, that the slightest evidence of ulceration or induration are suggestive of malignancy, and that pathologist must have a history and definite idea of the tumor's gross appearance and the proper section for a diagnosis.

Newton Smith concludes that rectal polyps are comparatively rare in infancy. When they do occur they seem to grow rapidly and should be removed.

Poston reports an acute intussusception caused by a lipoma in an adult. *McKinney's* paper epitomizes current concepts of colon neoplasms. *Kuru* reports a lymphosarcoma of the rectum. *Read* performed a successful colon resection in a five year old child for a solitary adenomatous polyp which had caused recurrent intussusception. In a case of my own not yet reported, a single adenoma 2x2½ cms. was excised from the upper sigmoid by colotomy. Recurrent partial obstruction but no intussusception preceded the operation. The child recovered.

In a case report by *Hughes-Jones* of enterogenous cyst, the etiology is discussed from the standpoint of the origin of the diverticulum and from the basis of sequestration. *Pattison* writes on 6 cases of malignant lymphoma. The localized type is of special interest to the surgeon.

Bowman describes a villous papilloma of the rectum with early malignancy, a rare benign tumor which undergoes malignant changes in 12 to 20% of cases. It should be removed when found. It has struck me that these papilloma resemble very closely intravesical papilloma.

PILONIDAL CYST

Twenty-one cases of pilonidal cyst were treated by *Ferguson*. After excision he used primary suture and had but one failure.

Oldham states he has had 100% cure in 19 cases of coccygeal sinus since 1933 by primary union following excision and suture with non-absorbable sutures.

Cattell excises the sinus after marking out a triangular flap. Excision is carried out, the flap mobilized and the wound sutured, closing the flap horizontally and longitudinally. My own experience with primary suture has convinced me that it has definite limitations. When once the incision becomes infected, as it very commonly does because of its site, the suture material acts as a foreign body to retain infection. Recurrence is perhaps more probable after primary union. As in any open granulating wound, a suspicious area may be curetted or excised; recurrences have been prevented in some of my own cases by careful post-operative observation. (See Transactions, 1934, Pilonidal Cyst, Rogers).

In a preliminary report of 6 cases examined by the Philadelphia post-graduate group in which pilonidal sinus or sinuses were injected with 5% methylene blue and X-rayed after Weeder's procedure; none of them showed communication with either sacrum or coccyx.

PRURITUS ANI

Hermance and Bacon in their contribution to Pierson's Cyclopedia of Medicine give a very concise description of the condition, the actual causes are briefly enumerated and accepted treatments given. Evaluating the treatments as they so well could have done would have helped the general practitioner but might have caused rejection of their copy in a cyclopedia.

Terrill writes as one who has cared for many cases of the disorder, he reviews the various theories and treatments and regards allergy as a factor in few cases and states "My opinion is that fully 90% of the cases that come to me are primarily of fungal origin, although many of them become secondarily infected with other organ-

isms." He advocates constant hot dressings of mercuric bichloride, 1-5000 in the acute stage, and the substitution of a milder solution or a powder if drug dermatitis develops; in the subacute or chronic state, an alcoholic solution of red iodide of mercury.

The Philadelphia post-graduate group report on Gabriel's A.B.A. solution, nupercaine in oil, sterile distilled water, autogenous vaccine, and undercutting operations. We are fortunate to have such reports available. A cure has not been found. The "Resume of Experimental Studies . . . ." by Bacon, should be read in full.

FISTULA IN ANO

N. D. Smith advises delay in incising the abscess until there is definite fluctuation: "incision is indicated as soon as the abscess points or when there is definite superficial fluctuation." *Many may not agree with this view.* He states that a common practice, that of inserting gauze-strip packing is painful and of doubtful value; on this there will be more general agreement.

Murdoch saves as much as possible of the external sphincter where the fistulous tract crosses it. "Several years ago I began saving the continuity of considerable sphincter muscle at the site of fistulectomy. A slight amount of freeing of the bowel wall above is done. It is then possible to place the sphincter upward and stitch the rectal wall downward over it fixing the sphincter against solid tissue in a somewhat higher but nevertheless good functioning position. The final result is a more normal anal contour without as much notched defect, this is sometimes marked after the usual operation."

This technic was applicable to about 40% of his cases, in the others the usual fistulectomy is performed.

Allen and Haskell used a two-stage fistulectomy in 119 of 226 cases. This is extending a sometimes necessary procedure beyond what most proctologists will regard as its indication.

FISSURE, PAPILLITIS AND PECTENOSIS

Morgan reports 83 cases, which he operated, whose lesions could be explained by the presence of pectenosis and a pecten band. He concludes that pectenotomy is the method of choice and advises against the practice of divulsion in dealing with this condition.

The Philadelphia post-graduate group treated 4 cases of fissure by injection of Gabriel's A.B.A. solution; it proved painful and unsatisfactory in these few cases. One c.c. quinine and urea hydrochloride injections fared little better in three other cases. Using smaller amounts, others have found them quite satisfactory in subacute small fissures. "Three fissures located in the posterior site were excised, after which the technic as outlined by Buie, namely, suturing the anal margin to the external sphincter muscle with catgut, was utilized. *All three cases* were followed by infection, and in one the sutures sloughed off."

INJURIES

Nightingale had a case of rupture of the sigmoid from compressed air. Unlike most of the cases, the nozzle of the air hose was not brought in contact with the anus by a practical joker. The workman was using the air to clean his clothes and accidentally touched the anus. There were several tears of bowel wall to but none through the serosa. Recovery followed laparotomy and repair of the bowel.

Black and *Weisman* in 1926 reported 27 cases, 19 of them fatal.

La Croix and *Ryan* cite the case of a farmer who suffered a common cause of rectal injury—that of impalement. This man slid down a load of hay causing the pitchfork handle, about 2 inches in diameter, to enter and lacerate the anus, rectum and sigmoid. The handle entered the bowel to a distance of 14 inches. He removed it himself. At operation a 6 inch rent in the sigmoid was found, most of the tear being in the mucosa, a relatively small portion through the serosa; a 3 inch laceration in the mesocolon was present. Recovery followed.

Epstein attended at the Lincoln Hospital a man who had inserted two apples in the rectum and who had at various times previously used a cucumber and parsnip in the same manner. On entry the patient had a 2 inch tear in the recto-sigmoid, localized peritonitis, and free soapsuds in the abdomen. Trauma from efforts at removal and a soapsuds enema explained these. The tear in the recto-sigmoid was not seen proctoscopically although the instrument was passed beyond its site. The star shaped appearance at the center of the apple, as seen in the roentgenogram, was a point of interest. The patient recovered.

INFLAMMATIONS

Several articles reveal the importance of the colon and rectum as foci infection. *Hirschmann's* discussion of the subject is definitely informative.

An unusual type of chronic buccal and peri-anal ulceration is described by *Wiseman* in which diagnosis was impossible and therapy of little avail. *Preusser* emphasizes the importance of anal infection in an article treating of the general phases of the subject.

SECTION VIII—*Editorial*

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastro-enterological Association is in no way responsible for editorial expressions.

CONCERNING THE ENIGMA, PEPTIC ULCER

I.

DURING the past three decades, considerable of the basic pathology of peptic ulcer has been established. Along broad lines, the effects of ulcer presence upon gastric and duodenal physiology now are appreciated. Physiologico-chemic investigations, conducted relatively recently, promise to cast light upon hitherto suspected, but not substantiated, phenomena concerned with the secretory and motor interdependence of the stomach, duodenum, the upper small bowel and biliary tract segments, and on the biochemic significance of "end" products of digestion in regard to a regulatory mechanism for digestive juice production, motor sequences and absorption in the presence or absence of peptic ulcer. In some aspects, these studies appear even to carry pointings with respect ulcer etiology and persistence. Experimental surgery, conducted under purposeful planning, has returned information of great worth as to what pathologic and physiologic deviations appear when anatomic disruptions deliberately are brought about and when, in the upper digestive tract particularly, the orderly, consecutive processes of food reception, digestion and absorption are interfered with. Studies of this character have raised a veritable mountain of facts, pathologic chemic,

motor, secretory, metabolic, nutritional, some of which appear to have bearing upon ulcer production or, its maintainence.

But, although facts have accumulated, there still exists much puzzlement as to how the majority of these facts is to be interpreted; particularly, what they mean, for example, in respect peptic ulcer. What do these facts signify apart from revealing how readily may develop stomach, duodenal and small bowel lesions of ulcerative kind, when foreign tissues are joined one with another; when secretions normal to one viscus are introduced into those to which they are strange and when such secretions perform no regular physiologic function; when nerves, blood vessels or muscles are forced to perform in uncoordinated or non-related fashion (anatomically and physiologically)—and so on? There are no limits to the speculative hypotheses which may be set up or to the fashion in which observed facts may be grouped and interpreted. Certainly, few of the experimental surgical procedures which result in peptic ulcer production or persistence or again, which prevent the development or initiate healing of ulcerations produced in the presence of disorganized anatomy, physiology or metabolism, basically seem to mean (even under the most liberal interpretations), little more than (*a*) evidence of how necessary it is in animals or man that anatomic integrity be preserved if normal function is to be expected, (*b*) how great may be the insult to normal structural *schemata* before there arise abnormal physiologic or biologic tissue departures, (*c*) how constant and strenuous are the efforts of disrupted anatomy and chemistry to adapt themselves to structural defects and to attempt to perform their normal work despite the serious handicaps imposed and *(d)* how, only in the presence of most radical anatomic maladjustments (*e.g.*—anastomosis of terminal ileum with the stomach; the "Mann-Williamson preparation," etc.), can functional disorganization be so profound as to overwhelm "natural" adaptability and so cause fatal issue. One marvels not so much that experimental surgery, as conducted, may cause visceral ulceration or that, when such ulcers have arisen, "substitution" structural arrangements or exhibited therapy may heal or, if instituted in time, prevent them, but that animals or man are endowed with such reserve digestive and absorptive mechanisms that permit injury (in the broad meaning) of a degree fundamentally almost opposite to that normal to the subjects, before pathology supervenes, digestive sequences are not carried forward sufficient for basic nutritional needs and *exitus* follows! It is well to recall that, in most instances, experimental surgery is being exhibited to animals which in their normal life-course, are not affected with peptic ulcer as one observes it in man: namely, a *spontaneously* arising lesion, which selects its own location, is grossly overwhelmingly "solitary" in incidence, is non-inflammatory, may or may not give rise to symptoms, or, until such complications, as the scar of healing, hemorrhage or perforation, may interfere but little with general nutrition or (provided the patient thinks he has but "dyspepsia" and is not gravely concerned by the knowledge that so "dread a disease as ulcer is gnawing at his vitals") with economic efficiency!

Thus, as to cause and not a little, as to effects, to internists and surgeons generally, and even to those internists—gastro-enterologists—who have acquired special knowledge of digestive tract disease, peptic ulcer still persists as a baffling enigma, clinically and, particularly, therapeutically. To those most familiar with factual data, the "ulcer problem" still is unsolved. Only individuals possessed of superficial or ancient knowledge, second-hand facts, the single-track mentality which finds comfort in set formulae and particularly, therapeutic regimens to which patients are fitted irrespective of their individual pathology or symptomatology—only to such readily satisfied persons does gastro-duodenal ulcer occupy any sort of satisfactory status.

To the experienced clinician, not the least distressing aspect of peptic ulcer is that which deals with its therapy. Inasmuch as comparatively little is accepted by those who are informed concerning the etiology of the lesion and since each subject's peptic ulcer is an individualized affection (as to position, size, histologic kind, tissue damage, secondary pathology, chemic effects) one must realize at present, that any "ulcer" *treatment can be only empiric. Actually, our "modern"* therapy is nothing more distinctive or positive than an attempt to relieve symptoms, to protect known or suspected damaged mucosa from dietetic and, vaguely, chemical traumata, to correct faulty visceral motility, to improve the patient's capacity for tissue repair by bolstering general nutrition and, when histo-pathologic complications menace life, to perform surgery appropriate to the special demands. However professionally distressing this admission may be, solid progress in peptic ulcer treatment will not be possible until the mechanism of ulcer production truly is established and universally admitted, the "life history" of the lesion recognized, its pathologic variations appreciated and the mass of therapeutic rubbish, accumulated on slim foundation during the past sixty years and now spread broadly on the pages of so-called "standard" text books, swept into final discard. Clear clinical thinking must replace dogmatic opinion, the exhibition of what is therapeutically curious or novel, faddism, the memorized formulae of student sophomorism and the pernicious practice of fitting ulcer subjects to *schemata* of "hand-me-down" diets and drugs which have descended from the days of Celsus *(De Medicina: "ad hibendi lenes et glutinosi sed citra solietatem: omnia acria atque acida removendi; vino utendum, sed neque procfrigido neque nemis calido").* As the therapeutic situation now stands, patients and physicians are lulled into a degree of smugness wholly unwarranted by facts. Certainly, at present, one can speak of "cure" only in its Continental significance of *"Kur"*: a *method of management* and *not a positive therapy* whereby restoration of normal visceral structure and function fairly definitely follows specific, directed effort.

So chaotic are the conceptions for and practices of peptic ulcer management, (particularly when one recalls that few lesions have so intensively engaged the efforts of so many investigators and clinicians for the past thirty years), that, at this late date and from a clinic whose experience doubtless exceeds that of any, one who has been veritably steeped in the ulcer problem now comes forward with what may be interpreted as a "where are we?" attempt at appraising today's ulcer therapy.*

*Andrew B. Rivers, M.D.—"A Consideration of Some of the Newer Methods for the Treatment of Peptic Ulcer," Mayo Clinic Read at the 29th Annual Session of the American Gastroenterological Association, May 4-5, 1926.

We are not acquainted with the kind of approach to the problem contemplated by Dr. Rivers but we believe it to be not out of line here to call attention to some aspects of peptic ulcer and its treatment which warrant consideration.

II.

(1) *What is it that is to be treated?* Most non-surgical "treatments" still are devised and exhibited on the theory that the "peptic" lesion is *gastric* and, that faulty gastric chemism requires correction if ulcers are to be placed in an environment most conducive to healing. In fact, the majority of standard text-books emphatically give the impression that gastric ulcer is the more frequent and the more important lesion. All clinical, surgical and post-mortem data prove that the duodenal lesion is of incidence to *the gastric anywhere from 3 to 1 to 6 to 1 depending* upon modes of classification and whose statistics are studied. If Mayo's anatomic definition of where the stomach ends and the duodenum begins, is accepted, then there is a ratio of four duodenal ulcers to one gastric. Despite this observation, in the vast majority of instances, the clinical mind still thinks in terms of the gastric lesion when non-surgical ulcer therapy is to be employed and, almost universally, the treatment regimen basically is arranged so that, theoretically, conditions favor the healing of a stomach defect *which includes a mucosal lesion of ulcer kind.*

These commonly exhibited modes of therapy are directed towards the protection or the healing of what is regarded as an open, "raw" mucosal area. Such "protection" is to be accomplished by "smooth" diet, or by drugs presumably which *select* and *adhere* to the "raw" surface and thus defend it from chemical or food trauma. Under this "protection-coat," spontaneous or medicinally stimulated mucosal repair is assumed to occur. Of the drugs employed, bismuth, gelatinous substances, aluminum or mucins are most favored. In association with such "protectants," various alkalies are given so that the "gastric juice" may be "neutralized" and hence its "corrosive" action upon the "raw" ulcer (even though such already may be covered by protective agents!) may be eliminated. In the majority of "ulcer regimes" proposed, a chief objective lies in bringing *gastric* chemism to a *neutrality* (so far as free HCl is concerned) even though clinical, operative and post-mortem studies disclose that duodenal ulcer is at least four times as prevalent as is gastric and few data are available regarding the free HCl in the duodenal content, with or without admixture of bile, pancreatic juice and *succus entericus.* Incidentally, it should be remembered that could one succeed in keeping a stomach without free HCl and thus preventing the action of pepsin, stomach digestion of the exhibited diet of milk, cream and eggs could not possibly occur: the chyme which then passes into the duodenum is not normal chyme but (apart from digestion of starch) is but an unsplit protein and fat food mixture which must depend for its digestion upon digestive agents distal to the pylorus. Duodenal contents lag but briefly in that gut segment, as Roentgen studies show, provided there is no organic obstruction or local ileus. Hence, if free HCl is neutralized *in the stomach, and eggs, milk, cream,* etc., are fed, the digestive burden falls largely upon the jejunum. Often has it been shown that severe local or general injury to the stomach's mucosa heals rapidly in the presence of high free HCl and pepsin.

Let us examine several of the above hypothesis upon which, in the vast majority of instances, peptic ulcer therapy depends and statistics relative cure are accumulated. *First,* as to the "open" or "raw" *mucosal defect* so commonly visualized by physician and patient alike, what are the facts?

In our own records, of 61 uncomplicated (non-stenosing, grossly bleeding or acutely perforating) gastric ulcers which came to operation at the height of digestive pain and discomfort, *11 only revealed non-epithelialization of their edges and bases. Fifty gastric ulcers* (quite as painful as the 11 above mentioned) *exhibited complete mucosal integrity; in fact, 33 of these "ulcers" (66%) actually were mural placques composed of well-delimited scars of various sizes and thicknesses.* Of these 33 lesions, 15 were so deeply mural as to present "soldier-spot" like scars on the peritoneal coat; another 4 "ulcers" had *"penetrated" through all the stomach wall coats* but complete perforation had been prevented by serosal scar plus reinforcement by the pancreas or the omentum. Such evidence at once imposes the conclusion not alone that with comparative rarity does peptic gastric ulcer present the "raw" mucosal surface which demands "protective" agents or calls for drugs or diet "neutralization" of free HCl and the consequent nullification of peptic activity, but emphasizes the very important fact that the great majority of peptic gastric "ulcers" is not "ulcer" as commonly understood, but is a *mural lesion* which, depending upon its extension towards the mucosa, may be or may not be complicated by such epithelial destruction as to give rise to a secondary ulcer-type lesion on its lumenal aspect. However, all evidence, histopathologically, indicates that the *initial lesion definitely is a wall defect;* the mucosal changes which have given it the name "ulcer" are nothing more than complications dependent upon factors which determine extension of the lesion so as to include that mucosa. Such complications may owe their occurrence to the fact that the tissues from the initial mural lesion towards the mucosa are less dense or resistant than are those towards the serosa, their blood vessels, being "terminal," most readily are occluded or destroyed; once such has happened, the resultant mural structures mucosalward die; they are digested by *any* proteolytic agent which may be present in the stomach's lumen and an ulcer-form *facade* is given to the primary mural lesion. Study of the initial mural defect whose extension towards the visceral lumen does *not* result in "ulcer," reveals that its progression towards the serosa is of a nature precisely like that which takes place when the extension includes the mucosa, but although in that progression, mural structures wholly may be destroyed, no "ulcer" complication is exhibited at the serosal limits unless complete perforation of the serosal wall occurs. One then has a "through and through" non-inflammatory "ulcer" which, when once it has arisen, makes difficult the opinion as to whether one is to lay greater emphasis upon mucosal than upon mural and serosal tissue loss. However, one may say that the "perforation" (when partial and not in association with a through and through lesion, *i.e.* the mucosal "ulcer"), is less serious than is that occurring when the initial mural defect breaks through the serosa and is not protected by peritoneal or omental

scar or backed up by such solid organ as the pancreas or the liver.

It is of the greatest interest to note that, while in our series of 61 operatively demonstrated gastric lesions, in 19, mucosal reparative integrity was adequate; the initial mural defect had extended as mural scar through, to, and including the serosa ("soldier-spot" lesion) in 15, and through even the serosa ("protected" perforation) in an additional 4. In all these 19 instances, the stomach wall had been preserved *in-so-far as preventing the passage of gastric contents* through it, but in each case, a through and through sterile or infected wedge of scar-tissue had replaced normal mural structures. Areolar tissue, glands, lymphatics, blood vessels, muscle layers, serosa had been destroyed and in their places there had been interposed a block of scar tissue. This wedge of scar locally, but seriously, interferred with coordinated neuromuscular functioning of the stomach, in degrees depending upon size and location. The location and the size of the wedge of scar could not fail to affect both secretory and motor activity, to a degree proportional with its destruction of normal structures. It would seem that motor interference is of great significance inasmuch as relatively few (9%) of the mural defects, whether or not bearing the mucosal ulcer-complication are located in segments of the stomach which have to do with the elaboration and excretion of free HCl. Since most of these scar wedges are located along the lesser curve, in the antrum or the pyloric section of the stomach, even wedges of but a centimeter or so would seem capable of interfering seriously with the intricately complex, criss-crossing and interweaving layers of muscle, richly supplied with nerves, which combine to form the structure of these gastric segments: segments which not alone are vigorously concerned with chymification but which actually differentiate so specially as to form the pyloric "ring."

(To be continued)

Frank Smithies

SECTION XII—"*The Clinic*"

Chronic Appendicitis

By

WILLIAM FITCH CHENEY, M.D.
SAN FRANCISCO, CALIFORNIA

IT is true that the appendix has many times been removed unnecessarily; that frequently it has been charged with producing symptoms for which it was in no way responsible; that repeatedly it has been wrongly accused by the physician or surgeon who hastily attributed to it disturbances of health which it did not cause and which its removal did not relieve. Thus the diagnosis "chronic appendicitis" has rightly come to be discredited and looked upon with more or less suspicion. Nevertheless the fact remains that in many instances chronic appendicitis affords the true explanation for certain chronic disturbances of gastric or intestinal function. Furthermore with care such cases can be identified with certainty and relieved by surgery, after dietetic and medicinal measures have all failed. A case recently observed has served to call attention anew to this situation.

A woman, aged 48, complained of distress after eating, with accumulation of gas relieved by belching it and passing it by bowel. For years past she had been constipated and her bowels rarely moved without assistance. She had to take a laxative every night and supplement this by an enema every day to secure a regular and satisfactory evacuation. Some years previous she had attacks of pain in the bowels, which she designated "colicky spells," occurring every few weeks; but more recently less often because of her routine of laxatives and enemata. Such attacks never lasted over one day and were not accompanied by fever. She observed no soreness or tenderness of the abdomen as a rule, except when her attacks of colic recurred.

This patient was small, pale, poorly nourished; but gave no evidence of organic disease anywhere in her body except in her abdomen. There tenderness was found over the right lower quadrant and a doughy mass, with muscle spasm but no definite tumor.

Laboratory examinations gave no evidence to elucidate her condition; but the explanation finally was supplied by an X-ray film of the colon after a barium enema. This showed the cecum dilated and low, hanging over the brim of the pelvis, with the appendix behind and below it. Both the cecum and the low retrocecal appendix were tender on palpation. The terminal ileum could not be made to fill at any time during the examination.

At operation the cecum was found covered by a Jackssonian membrane. The appendix showed signs of old inflammation and was somewhat distorted by bands of adhesions which were attached near its middle and to the retrocecal wall. It was swollen, firm and rather pale. Even more important was the presence of a sharp kink of the terminal ileum within the last 10 cm. above the ileocecal valve. The bowel there was folded upon itself and adherent for a distance of about 3 cm., the adhesions involving not only the wall of the bowel but the mesentery as well. The appendix was removed, the kinked bowel released and straightened and the mesentery freed. The patient had been told elsewhere before coming to San Francisco from her home in the country, that a diseased gall bladder was the probable cause of her symptoms, be-

Submitted May 16, 1932

cause the X-ray shadow after the dye was faint. But exploration of this organ with the abdomen open showed it perfectly normal in color, thickness and consistence. The patient made a rapid recovery and has remained free from her former discomforts ever since.

In this patient the outstanding symptoms were those of disturbed intestinal function. But in others such an adherent, deformed appendix may reflexly disturb gastric functions more than intestinal, either increasing secretion so that the picture resembles that of ulcer; or impairing both secretion and motility to such an extent that chronic gastritis with atony is closely imitated. In still another group gastric secretion may be found within normal limits in spite of the patients' complaints. Again, physical examination throws little or no light on the problem; gastric analysis may prove that secretion is abnormal but does not tell why; and fluoroscopy and X-ray films are necessary in order to demonstrate where the real trouble lies. The barium meal serves to eliminate ulcer or other organic change in the stomach and duodenum; but it requires a barium enema to prove with certainty the presence of abnormalities in the region of the cecum and appendix upon which the symptoms depend. These abnormalities comprise delay in the terminal ileum after the barium meal or its entire failure to fill after the barium enema; fixation of the cecum, tenderness over the inner side, cecal stasis and delay in its emptying time. The appendix itself may or may not be visualized. If visible it may be fixed and tender, unusual in shape and size, kinked or angulated or beaded or clubbed. Frequently it is slow in emptying, retaining barium for 48 to 72 hours or even longer. If the appendix is not visible, the absence of such signs in the X-ray films does not prove that it is normal, for it may be adherent behind the cecum and thus obscured by opaque material in the bowel, or its lumen may be obstructed so that barium can not enter; or it may be obliterated, atrophic or buried by adhesions. The following case is typical of the group now under consideration.

A man, aged 42, had for five or six years suffered from "stomach trouble" previously diagnosed as chronic duodenal ulcer. The symptoms had been recurring attacks of pain in the epigastrium, belching, water-brash, burning, nausea and vomiting, appearing one hour or two after meals, lasting for weeks at a time. Such attacks never entirely disappeared, even on routine treatment for ulcer, but would grow much less annoying for varying periods of remission. At the time he sought advice, he had no such pain, nausea or vomiting as described but complained of a heavy, dragging feeling in the pit of the stomach after every meal. No signs were found on physical examination over the upper abdomen but decided tenderness and a palpable finger-shaped mass in the appendix area. Gastric analysis demonstrated a high-grade hypersecretion, with total acidity 84 and free HCl 72. But X-ray films discovered no defect in stomach or duodenum, while they did show the cecum fixed, with the appendix indistinctly outlined and tender to pressure. After six months observation and treatment by diet and drugs the patient was no better; so operation was advised. When the abdomen was opened, a fibrous band was found extending from the base of the cecum to the abdominal wall; the cecum was twisted upon its axis and bound down to the wall of the pelvis by old inflammatory adhesions; the appendix was buried behind the cecum by adhesions that fixed it throughout its length. All adhesions and constricting bands were freed and the appendix removed. Five years have elapsed since that operation during which the patient has had no recurrence of his former attacks and has remained free from all gastric disturbances.

These illustrative case histories of chronic appendicitis could be multiplied many times from the written records of patients seen during the past 30 years. But the object is simply to call attention anew to the fact that chronic indigestion is frequently the consequence of old long-standing pathology in the region of the cecum and appendix produced by one or by several previous attacks or subacute inflammation involving these parts. Haste in reaching this conclusion, however, is most deplorable and has been the cause of numerous errors in the past.

The evidence which makes this diagnosis probable is first, a history of persistent disturbance of gastric or intestinal function or of both; but there is no history that is diagnostic and many variations occur. There may be mixed up with the digestive symptoms as account of more or less constant soreness and tenderness in the right lower quadrant and dull pain there at times, but this is not at all essential. Intercurrent attacks of cramps with diarrhea may form a part also of the clinical picture. From history alone, however, no conclusion can ever properly be reached. Physical examination likewise is untrustworthy. The signs it reveals are often vague and indefinite and may not be noted at all. They may be obvious at one examination and not discovered at all at another. Gastric analysis is variable in its results, inconclusive and never diagnostic; but of value because it aids in excluding organic gastric disease. Of all methods of investigation, X-ray examination is of the greatest value in chronic appendicitis, particularly after a barium enema; but even this may not always show the changes previously described to an extent that make them conclusive. It is only by combining the various items of evidence acquired that a trustworthy conclusion can ultimately be reached. Even so, in any obscure case, where manifestations are not urgent and delay does not imperil life, it is better to proceed slowly before advising surgery and to await developments while the patient is kept under observation, with dietetic and medicinal treatment calculated to relieve symptoms even though it does not modify pathology.

Post-Operative Hemorrhage Following Acute Ruptured Pre-pyloric Ulcer

By

GASTON A. CARLUCCI, M.D., F.A.C.S.
NEW YORK, NEW YORK

A FAIRLY thorough search of the American and foreign literature has failed to show any exhaustive articles on this subject. We have reviewed many papers devoted to post-operative complications following gastric surgery but no mention has been found regarding this condition. It is taken for granted, therefore, that this case of our's is an extremely rare one, and in view of its unusual features and the fact that the patient survived, it is reported in detail.

CASE REPORT

W. D., 26 years of age, a baggage reporter, was admitted to the Columbus Hospital Extension on April 24th, 1935, at 2 a.m., with a typical history of ruptured ulcer; sudden onset of pain four hours previously, slight vomiting, boardlike rigidity and tenderness of the abdomen. He stated that he had had gastric trouble for four or five years. He was fairly robust and had a good color.

Three hours after admission and eight hours after onset of symptoms he was operated on by Doctor Alvich, who found a calloused, prepyloric ulcer on the anterior wall of the stomach with a perforation about one-half inch in diameter; the peritoneal cavity was filled with gastric content. This was evacuated and the perforation closed by two purse-string, chromic sutures and a tab of omentum sutured over this area. A cigarette drain from the subhepatic space was brought out through a stab wound to the right side of the operative wound. The incision was closed in layers with silkworm for the skin.

During the first postoperative week the patient ran a slightly elevated temperature in the afternoon, sometimes as high as 101°, but his pulse rate stayed between 100 and 110. He was allowed to take liquids gradually and seemed to be in fair shape.

Then, on *April 29th*, there was some serous discharge from the incision and three sutures were removed. The following day he was unusually pale, and a note was made that there might be hemorrhage in the gastro-intestinal tract. The red blood cell count was then 1,800,000, and the hemoglobin 40%. Stool examination the next day showed strongly positive reaction for blood. A transfusion of 500 c.c. whole blood was given. On May 4th, the stool was still positive for blood and most of the wound had disrupted, being kept together only by adhesive.

On May 6th, the hemoglobin was 40% and the red blood cells numbered 3,320,000. *On May 10th*, the hemoglobin was unchanged but the red blood cells had dropped to 1,700,000. Another transfusion of 570 c.c. of whole blood was given on May 11. Two days later a third transfusion of like amount was given. The following day, the hemoglobin was 60%, and the red blood cells numbered 3,130,000. *On May 16th*, the fourth transfusion was given, this comprising 710 c.c. of whole blood.

Throughout this period of 16 days, every means was employed to stop the bleeding. Sodium citrate was given intramuscularly, as well as clyses, liver extract and even glucose, 50% solution, by mouth. The stools persistently showed strong positive reactions for blood despite these measures. The patient continued to vomit and was considered to be in poor shape.

It was decided, after consultation with the radiologist, Doctor Massaro, to attempt to localize the ulcer, if possible, by *Roentgenologic study*. A special preparation of barium mixture was given by mouth, in small quantities, and the patient was fluoroscoped for some time. The barium mixture was found to remain in the stomach except a small amount that entered the duodenal bulb. This appeared markedly narrowed and had the appearance of a small crater in the wall. After two hours the barium was still in the stomach.

Second operation: Despite the fact that the original incision had disrupted, it was felt that another laparotomy was indicated in order to save the patient. Therefore, on May 17, he was again explored through a midline incision, under gas oxygen anesthesia.

The disrupted wound had as a part of its base the anterior surface of the pyloric end of the stomach. This had to be freed in order to expose the right side of the abdomen; much of oozing resulted in doing so. The duodenum and pylorus were matted together in a mass of soft adhesions up against the inferior surface of the liver, and it was impossible to expose freely the duodenal area. We felt that the only procedure was to ligate the pyloric end of the stomach; this was done with a double silk ligature. A posterior gastro-enterostomy was performed, fairly easily, and a patchwork repair of the two abdominal incisions was made with through-and-through, interlocking silkworm gut sutures. The patient was then given repeated infusions of glucose in saline together with 100 c.c. of alcohol for every 1000 c.c. of solution.

The following day the temperature rose to 101°, the pulse to 150, but these dropped to 101° and 100, respectively, next day. From then on improvement was steady. The abdominal wound healed with very little discharge. There was very little distention and by May 25, eight days after the second laparotomy, there was only a trace of blood in the stools.

Then, however, the patient developed an *acute parotitis* on the left side. In spite of all applications, masticatics, massage and the like, the swelling increased. Although there was some discharge from the left auditory canal, an *incision had to be made in the left parotid gland on May 31;* a large amount of pus was evacuated; this on culture showed staphylococci. From the time of the incision of the parotid, improvement was steady; all wounds healed nicely, the patient ate more and more varied foods, and left the hospital two months after his initial admission.

Follow-up examination at the end of September showed a gain of 30 pounds in weight, the patient was eating nearly all solid foods without discomfort, and his abdominal wall exhibited but weakness between the two incisions.

DISCUSSION

In our opinion the facts that this patient had a disruption of his primary operative abdominal wound, had profuse, post-operative, gastric hemorrhage for at least 10 days, was able to withstand a second extensive exploration of the abdominal cavity, a posterior

Submitted June 15, 1936.

gastro-enterostomy in a contaminated field, and a suppurative parotitis, make this case truly unique.

The question of from whence the hemorrhage came, cannot be answered positively. At the time of the first operation no unusual bleeding was noted at the site of the ulcer perforation. At the second operation the duodenum and pylorus were matted together under the inferior surface of the liver and no strenuous attempt was made to separate them. The presumption is, however, that the bleeding came either from the sloughing margin of the original ulcer or from a point close by, as the patient never vomited blood; after ligation of the pyloric end of the stomach and gastro-enterostomy bleeding stopped.

Whether the closure of the pylorus with a double silk ligature was advisable is questionable. We felt, however, that the patient could not stand a resection and we felt also that a gastrojejunostomy alone would not stop the bleeding. As far as we have been able to determine, the patient now feels well, eats a varied diet and has no symptoms of indigestion or pain.

In the literature Berg (1), notes that, in cases of perforated peptic ulcer, multiple ulcers often occur. He reports two cases, both duodenal, which had a perforated and a bleeding ulcer at the same time. Bartrand (2), also cites two cases of severe gastric hemorrhage in the post-operative period following operation for perforated ulcer. One of these died; the autopsy showed a second ulcer on the lesser curvature, which was cicatrized, apparently not the source of the bleeding. In the other case, a secondary operation was done, gastro-pylorectomy; the patient recovered. An ulcer was found on examination of the portion resected, (not the perforated ulcer) but careful examination did not show any important arterial lesion in it. However, all gastric hemorrhages ceased after the second operation.

McCreery, in discussing this case, stated that in a series of 160 cases of acute perforation on his service at the Bellevue Hospital, the complication of severe, post-operative bleeding was encountered only twice. In the first case, the hemorrhage was so copious that the ulcer perforation was not recognized until it was located at autopsy. In the second case, the simultaneous occurrence of hemorrhage and perforation forced a delay of operation for six hours in an effort to get the patient in condition to stand laporatomy.

In conclusion, we would like to stress the fact that an apparently profuse hemorrhage may follow a perforated ulcer and it is only by close observation of the patient, his stools and by frequent blood studies that it may be recognized. With proper preoperative treatment, including especially the exhibition of frequent transfusions of whole blood, etc., a second laporatomy allowing extensive gastric surgery can be done even in a contaminated field.

NUTRITION

COSTELLO, JOS. P.

Obesity and Ocular Symptoms in Mentally Alert Children Due to Hypothyroidism. Endocrinology, Vol. 20, No. 1, 1936.

Many clinicians will recognize in this valuable contribution of Costello's a type of patient that they have seen in practice. The generally held opinion has been that in the presence of true hypothyroidism in children, obesity will always be associated with delayed bone development and mental torpor. In the type here described neither of these are found. In fact the patient, presenting a basal metabolic rate of from minus 14 to 26 is distinguished by her mental brightness and her interest in her environment and by some degree of ocular myopia. Dieting alone does not quickly reduce the weight or entirely fails to do so. Even with the administration of thyroid, results are very slow partly because large doses are badly tolerated and small doses over a long period of time are necessary. It is also to be noted that while thyroid greatly improves the weight and the visual defect it actually cures neither. In the few cases of Costello's syndrome which the reviewer has treated two other features were noticeable: excellent attempt at co-operation and a pathological proclivity to lying.

The Feeding of Modified Gastric Juice in Pernicious Anemia. J. A. M. A., Vol. 106, pp. 2058-2059, June 13, 1936.

Greenspon recently offered an explanation of the role played by the gastric juice which was different from Castles' theory of the interaction of intrinsic and extrinsic factors.

Greenspon's experiments were recently repeated in five typical and untreated cases of pernicious anemia. His technic was adhered to throughout the experiments. The gastric juice used was taken from fifteen normal, healthy medical students, and histamine (0.1 mg. per kilogram body weight) was used to stimulate its flow.

The patients were all typical cases of pernicious anemia. They were all given large amounts of gastric juice (1750-2370) daily for a period of time varying from four to nine days. In one case the reticulocyte count went up to three per cent, while in the other cases it never went over one per cent. After the administration of liver extract there was the usual reticulocyte response with aleviation of symptoms.

From these results the conclusion was reached that modified gastric juice has no beneficial effect in pernicious anemia.

WAKEFIELD, E.E., AND ELLINGER, S. C.

Diet of the Bluff Dwellers of the Ozark Mountains and Its Skeletal Effects. Ann. Int. Med., IX, 1412, April, 1936.

This rather unique study was made on skeletons and parts of mummified bodies in the University of Kansas. The undigested food residue seen in the feces was studied with the hope of de-

anxious to end the test. The first seven protocols illustrate the various types of response obtained and are self explanatory. The results have been grouped together in the construction of the composite curve shown in Graph I.

It should be recalled that the average fasting secretion among normal persons is 20 c.c. or more per ten-minute period, according to Bloomfield (8). Our studies, on the whole, corroborate this statement. We have considered a secretory rate of less than 5 c.c. per ten-minute period as marked reduction in volume and a secretion above this figure but less than the fasting control figure as a moderate reduction in volume. Those cases in which the free acidity dropped to zero after the administration of the drug have been classed as a marked reduction in acidity regardless of its duration. Those cases in which the free acidity dropped below the previous fasting level but did not reach zero have been classed as a moderate reduction in acidity regardless of its duration. Those who showed only slight or indefinite changes were grouped under the headings of "No effect." Using these criteria our results are summarized again in the following table:

Summary of Results

	Volume (No. of cases)	Free Acidity (No. of cases)
Marked Reduction	20 (64.5%)	10 (32.2%)
Moderate Reduction	10 (32.2%)	7 (22.6%)
No Effect	1 (3.3%)	10 (32.2%)
Increased		4 (13.0%)
	31	31

From the results described, it seems that morphine in ordinary therapeutic dosage has a fairly uniform inhibitory effect on the gastric secretion in man under fasting conditions. The reduction of the volume of the basal secretion was more marked than that of the free acidity, although in one out of every three cases achlorhydria took place for sometime after the administration of morphine and in approximately half of the series there was a distinct lowering of the acidity in comparison with the fasting values.

That the very first specimen of the fasting stomach content usually does not represent the actual basal secretion is well illustrated in the protocols. Its volume as well as its acidity are easily affected by many factors, particularly in this series where most of the cases were ulcer patients. Attention is also called to the fact that the mere presence of a tube in the stomach seemed not infrequently to provoke some rise in the free acidity as shown in Graph II and some of the protocols. Should morphine be given right after the very first or second fasting specimen, one might very well be led to think that a brisk stimulation did take place at the beginning, as the depressing effect of the drug usually manifests itself only about 20 minutes after the medication.

The depressive effect of morphine on gastric secretion seemed to have a close relationship with the mental state of the patient. The more drowsy he became, usually the more marked was the depression. Those who became talkative or remain active after the medication gave the least response, and, in fact, occasionally a contrary effect.

From Graphs III, IV and V, it may be seen that morphine is not a strong inhibitor of gastric secretion. Its depressive effect could be readily over-shadowed by a new stimulus, whether it were a purely psychic one such as the taking of food by the patient in a neighbouring bed or a chemical one such as an injection of histamine. In the instances in which morphine seemed to act as a stimulant, the effect was a very weak one compared with that evoked by histamine or by a psychic stimulus.

The question of why morphine affects the volume of the basal secretion more than it does the free acidity is very interesting and one which we are not able to answer to our complete satisfaction. Keefer and Bloomfield (9) in 1926 and Porter (10) in 1931 observed the same phenomenon in their studies on the effect of atropine on gastric secretion.

DOG EXPERIMENTS

A series of experiments were carried out on two dogs with isolated stomach pouches. One of the two was a dog provided with a complete stomach pouch with an intact nerve and blood supply after the technic of Dragstedt (11), and the other with a classical Pavlov pouch. Morphine was used in 0.001 gm. doses, corresponding roughly in a 15 kg. dog to a therapeutic dose of 0.015 gm. in a 60 kg. human subject, but occasionally a bigger dose up to 0.012 gm. was also tried. No attempt was made to study the effect of larger amounts. The first dog was observed for a period of 45 days, and the second one for about 20 days.

The results obtained from these two dogs were quite inconsistent. Protocols VII and IX are illustrative of the variations observed under conditions as constant as we were able to maintain. Graphs VI and VII are composite curves representing the average values obtained. These are also summarized in the following table:

Complete pouch dog — *Pavlov dog*

	Vol. per 30 min.	Free HCl	Total acid	Times observed	Vol. per 30 min.	Free HCl	Total acid	Times observed
Basal	32	74	78	31	8	0	11	24

From the results shown above and elsewhere, it would appear that the dog does not react quite the same to a small dose of morphine as man. It was actually more difficult to control the surroundings of the dogs than it was those of the human patients. With the complete pouch dog, the control became a complicated problem. The constant loss of fluid and acid through the fistula, the necessity of feeding the animal several times daily instead of once a day as in normal dogs, the question of dehydration if starved too long,

the amount of salt added to the food to replace the chloride loss, the psychic factor such as hunger and thirst—all seemed to be able to influence the results directly or indirectly. It was practically impossible to control the situation satisfactorily. The Pavlov dog, on the other hand, presented a much simpler problem since the greater portion of the stomach was intact. However, this dog was not altogether desirable for our purpose for it did not secrete enough fasting juice, and

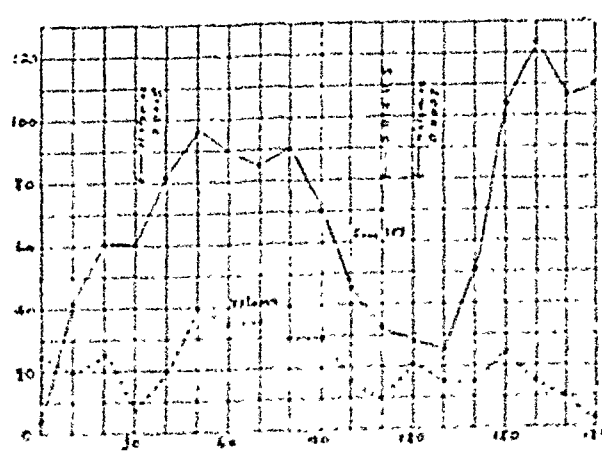
what is more, it did not secrete any free acid at all under the basal condition.

The operation for a complete pouch in dogs is a difficult one involving a very high mortality rate. The dog requires the most delicate post-operative care for a number of weeks before it sufficiently recovers from the operation and can be considered normal. In carrying out our experiments, attempts were made to make the conditions alike as far as possible, with particular attention to the time of feeding and the taking away of food and water at certain definite hours before the test experiment.



In spite of the precautions taken, the results obtained were very different. Even the fasting experiments varied considerably on different days. Since our observations do not represent an extensive study, it

seems best not to draw any positive or final conclusions from them. Nevertheless, it may be noted that the Pavlov dog showed a transient rise in volume and acidity after the injection of morphine on most occasions, while the complete pouch dog showed more inhibition than stimulation. The amount of stimulation in both dogs, however, was far less pronounced than those evoked by either food or histamine.

It is our impression that dogs are not entirely suitable for studying the subject in question, and the results obtained from them are not comparable with those obtained from human beings. The most obvious reason is that the dog and man do not react the same to morphine. A small dose of morphine readily causes a dog to become nauseated, and to vomit and defecate. There is a definite state of restlessness during the first

hour or so after the administration. These are rarely observed in man.

The question of tolerance or addiction to the drug was also considered during our observations, although we tried not to give the drug regularly to the dogs. However, there was evidence to suggest that tolerance did play some part, as the dogs seemed to develop fewer symptoms with the same dose of morphine towards the later part of the period. The gastric secretions, nevertheless, showed no striking changes.

SUMMARY

Morphine in therapeutic dosage in man exhibited in the majority of instances an inhibitory effect on the fasting gastric secretion. Over 95% of the cases

studied showed a reduction of volume and approximately 50% a corresponding drop in the free acidity. Only in 4 instances did a mild increase of the acidity take place after the injection of the drug. The depressive effect was found to be more marked when the patient was quiet and drowsy under the influence of morphine. The inhibitory action of morphine was, on the whole, rather weak for it was easily overcome by stimuli of chemical, psychic, or gastronomic origin. The effects of small doses of morphine in the dog were inconsistent. In one dog, morphine seemed to produce a mild stimulation, while in the other, both stimulation and inhibition were observed on different occasions. The difference in results between man and dog is probably due to the fundamental difference in their respective reactions towards the particular drug.

E. Histolytica and Other Protozoa in the Personnel of a Chicago Hospital*

By

H. E. McDANIELS, M.D.

ELEANOR BURTON, M.D.

and

LLOYD ARNOLD, M.D.

CHICAGO, ILLINOIS

DURING November and December of 1935, nine active cases of amebic dysentery were found among the personnel of a Chicago hospital. The medical department of the hospital examines and treats all employees who report themselves sick and unfit for duty. In the course of such examinations in the two months mentioned above, 11 persons were found to have Entameba histolytica in the feces. Nine of the 11 complained of gastro-intestinal symptoms. Specimens from the other two persons contained principally cystic forms of the parasite, and there was no diarrhea or other intestinal complaint.

These findings and the general alarm among the remainder of the personnel made necessary a thorough investigation of the extent of amebic infestation; and at the same time the plumbing was carefully checked. Food-handling procedures were also investigated and the first fecal specimens to be examined were those from the food handlers.

Although the main subject of this report is the result of the fecal examinations, a brief summary of the plumbing defects will be given here. An inspection† of the water supply and sewerage facilities of the main hospital building, annexes, and nurses' home was made November 29th and 30th, 1935. The water supply for the entire institution is obtained from the City of Chicago. Water is taken from Lake Michigan, chlorinated and delivered to all consumers without further treatment. Chicago water pressure is not sufficient to serve the upper floors of the institution directly, and booster pumps are needed to raise the pressure sufficiently for service on these upper floors. There are, therefore, two general cold water piping systems in the institution and in addition an iced drinking water system consisting of a cylindrical steel cooling and storage tank, and a small electrical booster pump.

Field analyses of water collected during the inspection showed it to be bacteriologically safe and to have a residual chlorine content of 0.2 part per million. Sanitary wastes from the entire institution are discharged into the Chicago sewer system. The institution is equipped with scores of water-flushed toilets, lavatories and sinks in addition to many other plumbing appliances, such as hydro-therapeutic baths, utility sinks where bed-pans and urinals are washed, instrument sterilizers, etc. Many places were found where possible back-siphonage of sewage might occur. All toilets in the institution are of the "flushometer" valve type where the water supply has a direct pressure connection to the toilet. In case of stoppage of the toilet, the level in the bowl could rise until the water inlet would be submerged. If this occurs at a time when the water supply is cut off for any reason, the opening of a cold water tap in the same line below the flooded toilet would cause sewage to be siphoned into the water supply. None of the toilets in the institution were equipped with siphon-breakers at the time of the inspection. All utility sinks and most of the lavatories were found to have faucet inlets located below the top rim of the sink, making it possible for these inlets to be submerged whenever the drain might become clogged. At times when these inlets are submerged, if a water shut-off occurs, back siphonage of bed-pan and urinal washings may take place. This would introduce dangerous contamination into the water supply.

It was found during the inspection that five of the six instrument sterilizers on the operating floor had direct overflow and drain connections to the sanitary sewer. If the drain line to these sterilizers were to become clogged, sewage might actually run into the instrument sterilizers. With such occurrence it might be possible for instruments used during operations to become seriously contaminated; in addition, the water supply would be subject to possible pollution.

In order to make the water supply and sewerage facilities safe and sanitary, the following recommendations were made:

1. Make a complete plumbing survey of the entire institution in order to locate every place where it would be possible for back-siphonage to occur from plumbing fixtures to the water supply system, and correct such conditions.

2. Install satisfactory siphon-breakers on all toilets equipped with "flushometer" type valves.

3. Change the water service inlets where necessary at all lavatories, sinks, slop sinks, hydro-therapeutic baths, etc., so that all inlets will be at a level high enough to preclude the possibility of their being submerged at any time.

4. Prohibit the use of hose at slop sinks or on any other equipment where such practice may permit back-siphonage to occur even though the plumbing fixtures may be properly designed and installed.

5. Provide atmospheric vents on the drain lines from all instrument sterilizers.

6. Incorporate immediately a practice at the institution that no plumber or other person shall be permitted to close a valve on a water supply main without authority of the master mechanic, who shall first notify all persons in charge of those parts of the building which will be affected by such shut-off so that no

† The inspection was made by the Division of Sanitary Engineering, Illinois Department of Public Health. The sanitary features presented here are from the report submitted by this Division.

Submitted June 8, 1936.

attempt will be made to draw water from the shut off portion of the system until repairs are completed and water under pressure is again available. This practice should be continued until all plumbing fixtures have been corrected where necessary to prevent back-siphonage of sewage to the water supply system.

The foregoing recommendations were carried out exactly as outlined. In addition to the regular maintenance crew, extra plumbers were employed and the work of correcting plumbing defects was begun and carried to completion as soon as possible. Siphon-breakers, totalling 192 in number, were installed on all toilets, utility sinks, and other equipment in which submergence of the water inlets might occur as a result of clogged drains. Lavatories and other sinks were fitted with new faucets of such design that the delivery spouts were above the highest level of the bowl rims. Drains to all sterilizers and water stills were changed to open funnel types, so that any back-flow of sewage would run out on the floor and not into the apparatus.

PROTOZOA SURVEY

Arrangements were made to examine fecal specimens in one of the laboratories of the hospital. A daily schedule for the submission of specimens was laid out according to divisions of the hospital personnel. Kitchen employees were examined first, the nurses next, and later the clerical and maintenance forces, laborers, janitors, and miscellaneous groups.

Specimens were collected in paraffined paper cups and delivered to the laboratory within one hour in most cases. None of the specimens were more than two hours old in any case. Cups containing the feces were either examined immediately upon receipt, or placed in a 37° C. incubator until examined. In spite of the detailed instructions issued, a certain number of specimens contained oil. These samples were rejected by the laboratory and were not counted in our totals of examinations per person. Additional material was requested in such cases.

Direct smears in water or eosin were examined, and iodine was used for the identification of nuclear structures. In certain cases methylene blue in methyl alcohol, as described by one of us (1), was used. This stain was useful especially for trophozoites which did not exhibit a sufficiently characteristic appearance, and which failed to show nuclear structures clearly with iodine. Four to six direct smears were thoroughly searched in the negative cases. Positive smears were examined until the species identification was assured and until the examiner was satisfied that any double or multiple infestation would have been detected. All protozoa found were recorded. Specimens showing precystic forms of amebae or unidentifiable trophozoites were so recorded, and additional specimens were immediately requested.

All specimens were inoculated into the liver agar and serum medium of Cleveland and Collier (2), and were examined after 24 and 48 hours incubation. No concentration methods were attempted, nor was any use made of fixed and stained smears. Comparative stool and complement-fixation tests were planned, but not enough blood specimens were submitted to the laboratory to be of statistical significance.

Three hundred eighty-four persons were examined at least once. The greater part of these (287) were examined three or more times. All kitchen employees (68) were examined four times. Eleven hundred and two examinations were made on 384 persons, giving an average of 2.9 examinations per person.

RESULTS

The percentage distribution of amebae and flagellates is shown in Table I. The total is larger than the actual number of persons examined because of multiple infestations in 42 of the subjects.

TABLE I

Intestinal Protozoa found in personnel of a Chicago Hospital (384 persons)

Protozoa	Persons	Percent
E. histolytica	24	6.3
E. coli	102	26.5
E. nana	69	18.0
I. butschlii	9	2.3
C. mesnili	11	2.9
G. lamblia	10	2.6
T. intestinalis	1	0.3
Negative	201	52.3

Dientameba fragilis was not encountered in this group of specimens. Single species of protozoa were found in 141 persons; 41 had two species, and one person was infested with three species of protozoa. Of the 24 persons harboring E. histolytica, 13 were discovered on the first examination. Five additional ones were found during the second examination. The remaining 6 were diagnosed in the third to fifth examinations. Table II shows the above data in a cumulative form.

TABLE II

Cumulative findings of E. Histolytica by repeated fecal examinations in a group of 384 persons

Examinations	Number Found	Percentage of Total
One	13	54.2
Two	18	74.2
Three	19	79.2
Four	23	95.8
Five	24	100.0

During surveys such as this, the microscopist often suspects the presence of E. histolytica in a certain number of specimens without actually finding perfectly typical forms on which to base a diagnosis. Such suspected cases or carriers should be removed at once from food-handling duties or other situations in which they might be likely to infect other persons. Additional specimens may then be obtained and the diagnosis definitely made. Considering this survey on the above basis, 95.8% of the positives were identified *or suspected* in two examinations.

Since all specimens were cultured, a comparison can be made of the relative efficiency of cultures and direct microscopic smear examinations. In six instances the smears were positive for E. histolytica on specimens

for which the cultures were negative. In one instance the culture was positive while the smears were negative on first examination. Amebae were detected in the examination of a second specimen from this person.

The positive findings of E. histolytica were on persons widely scattered throughout the institution. No particular occupational group or single department had a disproportionately large number of positives.

DISCUSSION

The 6.3% of persons found positive for E. histolytica is within limits ordinarily given as the normal incidence for the United State. These findings are higher, however, than those Kaplan, Williamson and Geiger (3 and 4) reported for Chicago food-handlers in 1927 and 1929. Their first report on a group of 720 food-handlers showed an incidence of 2.22% positive E. histolytica. The second report on 1,148 personssons gave an incidence of 2.35%. Statistical data on the findings in the Chicago outbreak of 1933 have not as yet been published. Johnstone Davis and Reed (5) found 9.2% E. histolytica infestation in 1,000 prisoners at San Quentin in 1933. In the same report they tabulate findings of other investigators on various groups of subjects, totaling 11,565 individuals. The average histolytica incidence for this large number of persons, all of whom were examined in California, was 12%. Since the above data are for residents of California, they are not properly comparable to what might be found under different conditions in Chicago.

Our findings on the hospital personnel do not point definitely to any one source of infestation. The sanitary inspection revealed many conditions which would allow possible pollution of the water supply. With such a large number of plumbing fixtures it is inevitable that water shut-offs are frequently necessary in order to make repairs and to clear drains which have become stopped. The possibility of transmission by food-handlers is also present. Among the kitchen employees there were three persons infested with E. histolytica. Whether they received their infestation by the same means and at the same time as the others, or whether they were the source from which the others were infested, is of course unknown. In addition to the foregoing possibilities, there is also the factor of outside sources from which any of the group might have acquired the parasites.

Correction of the plumbing defects is expected to end the possibility of water transmission. To remove the likelihood of transmission by food, all cases and carriers were treated until proved negative by at least four stool examinations. All new employees are to be examined four times before approval for service in the hospital.

SUMMARY

1. Nine cases of amebic dysentery and two carriers were found among sick employees of a Chicago hospital. A survey of the remaining 384 employees revealed 24 additional carriers of E. histolytica.

2. An inspection of the water and sewerage arrangements revealed numerous faulty conditions by means of which the water supply might have become contaminated. Transmission by food-handlers was also possible, since three of the kitchen employees were infested.

3. Careful microscopic examination of fresh fecal specimens was found to be superior to the cultural methods employed in this survey.

4. Examination of two specimens per person was sufficient to reveal or place under suspicion 95% of the carriers actually found.

5. The control measures consisted of correction of all plumbing defects and treatment of all cases and carriers until free from E. histolytica, as shown by repeated negative stool specimens. New employees must be free from infestation before being accepted.

The Colon in Mental Disease*

I. Dementia Praecox

By

PURCELL G. SCHUBE, M.D.

BOSTON, MASSACHUSETTS

ALTHOUGH much has been written about the emotions and the effect produced by them upon the gastro-intestinal tract, a comparatively few objective studies have been carried out upon man, and even fewer upon him when his emotions are most abnormal, i.e., when he is psychotic. It is certainly reasonable to expect to find in the psychotic individual the most pronounced and prolonged of emotional states; this being unquestionably true, and if emotions alter the functioning of the gastro-intestinal tract, then the most profound and prolonged of functional alterations should be observed in the gastro-intestinal tracts of psychotic individuals.

It is the purpose of this paper to present a study of one portion of the gastro-intestinal tract, the colon, in one type of mental disease, dementia praecox.

*From the [illegible] Boston State Hospital.
[illegible] June 2, 1934

a. Indifferent	10	11	6	2	2	2	2
b. Agitated	2	1	0	1	1	1	0
c. Tense	2	2	3	0	0	0	0

METHOD

The individuals used for this study were all definitely mentally ill and sufficiently so to be admitted to the hospital for an indefinite period of treatment. The psychosis, dementia praecox, was considered as a clinical entity with the principle features limited to (a) primary progressive deterioration, (b) autistic or deristic withdrawal from the environment, and or (c) intellectual incoordination. The psychosis in each individual was considered to be chronic. All of the patients were men, women being excluded from this initial work because of the possible complicating factors of catamenia.

Each patient was given two cleansing enemas, one following the other, about two hours before the examination and shortly after the noon-day meal. No attempt was made to interfere with the regularity or quantity of food eaten. At the prescribed time the patient was given a barium enema, the barium mixture being run in under gravity until the colon was apparently filled. The maximum quantity of barium mixture given to any one patient was 2,000 c.c. The filling was determined by leaving the rectal tube in place until no more barium would flow into the colon. The entire procedure was followed under the fluoroscope.

The patient was permitted to evacuate then as much of the enema as he wished, and his colon again observed under the fluoroscope. The rate of emptying and the tonus of the colon were studied every other day under the fluoroscope until the colon had emptied itself of barium. Throughout the procedure the patient was permitted to resume his regular dietary habits and physical activities. The maximum normal emptying time of the colon was considered to be 48 hours. The emptying time and the tonus were correlated with each other and with the body type and mental state of the individual.

RESULTS

In the 48 cases of dementia praecox studied, the ages ranged, at the time of the study, from seventeen to forty years. Some of the patients had been mentally ill for as long as ten years. No individual had been ill less than one year. In no instance could anything abnormal be found in the size, shape, position or contour of the colon. The musculature of the abdominal wall was good in forty-four and poor (lax) in four of the cases. In the four cases with poor abdominal tone no relationship could be established between the poor tone and the colon emptying time and tonus. The dominant emotional states, subjective and objective, of the patients were classified as, indifferent 35, agitated 6, and tense 7. The tonus of the colon was decreased in sixteen cases, normal in twelve cases and increased in twenty cases. The emptying time of the colon was 48 hours for 14 cases, 96 hours for 14 cases, 144 hours for 9 cases, 192 hours for 3 cases, 240 hours for 3 cases, 288 hours for 3 cases, and 336 hours for 2 cases.

The relation between the emptying time and tonus of the colon and between each of these and the body type and mental state of the individual is shown in Tables I and II.

TABLE II

Showing relationship between colon tonus and body type and mental state

	COLON TONUS		
	Decreased	Normal	Increased
1. Body Type			
a. Pyknic	2	4	8
b. Athletic	0	2	4
c. Asthenic	14	6	8
2. Mental State			
a. Indifferent	14	9	12
b. Agitated	0	1	5
c. Tense	2	2	3

From a study of the material presented in these tables the following facts are evident:

1. The tonus of the colon was normal in 25 per cent of the cases and abnormal in 75 per cent of them. Of the cases in which the tonus was abnormal, in 44

per cent it was decreased and in 56 per cent it was increased.

2. The emptying time of the colon was normal in 29 per cent of the cases and abnormal in 71 per cent. In those cases in which it was abnormal 41 per cent emptied in 96 hours, 26 per cent in 144 hours, 9 per cent in each of 192, 240 and 288 hours and 6 per cent in 336 hours.

3. Where the colon tonus was normal only 16.6 per cent of the cases emptied within the normal period, whereas 33 per cent emptied in 96 hours, 25 per cent in 144 hours, and 8 per cent in each of 192, 240 and 288 hours. Where the tonus was decreased 25 per cent of the cases emptied within the normal period, 25 per cent in 96 hours, 12.5 per cent in 144 hours, 6 per cent in each of 192 and 240 hours, and 12.5 per cent in each of 288 and 336 hours. Where the colon tonus was increased 40 per cent of the cases emptied within the normal time, 30 per cent in 96 hours, 20 per cent in 144 hours, and 5 per cent in each of 192 and 240 hours.

4. When the relationship existing between the emptying time of the colon and the body type of the individual was investigated it was found that where there was a pyknic body habitus the colon emptied normally in 14 per cent of the cases, in 96 hours in 57 per cent, in 144 hours in 14 per cent, and in each of 192 and 240 hours in 7 per cent of the cases. Where the body habitus was athletic the colon emptied normally in no instance, but 66.6 per cent of the cases emptied in 96 hours, and 33.3 per cent in 144 hours. Where the body type was asthenic 42 per cent of the cases had colons which emptied normally, 7 per cent emptied in 96 hours, 18 per cent in 144 hours, 7 per cent in each of 192 and 240 hours, 10.7 per cent in 288 hours and 7 per cent in 336 hours.

5. When the relationship existing between the tonus of the colon and the body type of the individual was investigated it was found that in those cases with pyknic body habitus 28.5 per cent had a normal colon tonus, in 14 per cent of the cases it was decreased and in 57 per cent it was increased. In the cases with athletic body habitus 33 per cent had a normal colon tonus and 66.6 per cent had an increased colon tonus. In those cases with asthenic body habitus 21 per cent had a normal colon tonus, 50 per cent had decreased tonus and 28.5 per cent had increased tonus.

6. When the dominant emotional state was investigated relative to its relationship to the emptying time of the colon it was found that of the cases whose emotional state was characterized by indifference 28.5 per cent had colons emptying normally, 31 per cent emptying in 96 hours, 17 per cent in 144 hours and 5.7 per cent emptying in each of 192, 240, 288 and 336 hours. Where the dominant emotional state was agitation 33 per cent of the cases had colons which emptied normally and 16.6 per cent emptied in each of 96, 192, 240 and 288 hours. Where the dominant emotional state was characterized by tenseness 28.5 per cent of the cases had colons which emptied normally, 28.5 per cent in 96 hours and 42.6 per cent in 144 hours.

7. When the dominant emotional state was investigated relative to its relationship to the colon tonus in those cases whose emotional state was characterized by indifference 25 per cent had normal colon tonus, 40 per cent had decreased tonus and 34 per cent had increased colon tonus. In those cases whose emotional state was one of tenseness 28 per cent had normal colon tonus, 28 per cent had decreased tonus and 43 per cent had increased colon tonus. In those cases whose emotional state was one of agitation 16.6 per cent had normal colon tonus, and 83 per cent had increased tonus.

DISCUSSION

In 1930 Alkan (1) wrote that the psychic processes influence the small intestine and colon in various ways; that according to our knowledge they alter secretion comparatively rarely, but the motor functions all the more frequently. The small intestine, he feels, is the end-organ of psychic alterations, but that these alterations manifest themselves much more frequently in the colon, in a spastic as well as in an atonic manner; that every kind of psychic excitation may show itself in constipation, which is, for the most part, spastic.

Alkan quotes Fleiner as saying: "Diagnostically these X-ray pictures of the colon are often of more value than the patient's facial expression, which can be controlled voluntarily or distorted conventionally, the result being an expression which is harmless and well balanced. The expressive movements of the colon as they appear in the picture, on the other hand, do not deceive, they are unfalsifiable and unmistakable. Questioning many patients as to their attitudes and experiences and moods, only after having looked at their intestinal pictures, I then obtained unrestricted information."

Substantiating these observations are those of Adolf Meyer (2) who in a paper which he read before the American Gastro-enterological Association in 1932 stated, "Instead of leaving the impression that in most cases we have to probe at once into the sex life when we suspect 'mental factors' to be playing a role, I should emphasize the fact that after all practically every fundamental function can take a lead in the personality constitution, in this sense, that, for instance, the gastro-intestinal function may have just as much of a tendency to express the personality as the sex function and *to be* 'the personality' in certain situations and in certain periods of life. I should say that the gastro-intestinal receptive, digestive and eliminative functions can become that which expresses, and leads to the government of, the person for certain periods of the day or throughout life as a dominant and leading concern."

This personality, states C. Macfie Campbell (3), if adequately conceived, represents the total system of forces, including both those conscious and expressed and those subconscious and repressed. Furthermore, he continues, the personality and the psychosis are not independent concepts: the psychosis is the personality; it is the individual in action; one phase of an individual existence.

This personality consists, then, of the sum total of chemical, physiological, emotional, overt and intellectual spheres of an individual which under average conditions in a normal person have a socially satisfactory balance. When an individual becomes psychotic, *i.e.*, when his personality deviates from the socially accepted standards of conduct there is some abnormality in the balance of the chemical, physiological, emotional, overt and intellectual spheres. In dementia praecox there is usually a definite abnormality in the emotional, overt and intellectual spheres, and this was found to be particularly true of the cases used in this study. Since there are marked personality deviations in dementia praecox, and since the gastro-intestinal tract

may have a tendency to express the existing personality, this study of the colon should reveal some facts relative to the physiological aspects of dementia praecox.

A survey of the results presented in this paper would tend to indicate:

(a) There is a certain number of individuals in a dementia praecox group in which there is an abnormality in the emptying time and/or tonus of the colon.

Thus in 75 per cent of the cases the tonus was abnormal of which group it was decreased in 44 per cent and increased in 56 per cent. Furthermore in 71 per cent of the cases of the entire group the emptying time was abnormal; *i.e.*, delayed. The tonus and emptying time of the colon were both decreased in 25 per cent of the group. The tonus was increased and the emptying time decreased in 25 per cent of the group. Therefore in dementia praecox, although it is highly probable that the tonus or the emptying time of the colon will be abnormal (3 chances in 4), the probability of the tonus and emptying time being abnormal is less (1 chance in 2) and the probability of the tonus and emptying time both being decreased still less (1 chance in 4). On the other hand the chances of the tonus and emptying time of the colon both being normal are 1 in 24. It is thus perfectly obvious that although it is possible that the tonus *or* emptying time of the colon may be normal (tonus or emptying time either have about 1 chance in 4 of being normal) the chances of both being normal in the same individual are rather remote (1 chance in 24). This being so one would be justified in concluding that in dementia praecox in the majority of cases there would be found an abnormality in the emptying time and/or tonus of the colon.

(b) Inasmuch as there was no clinically discernable pathology capable of producing the observed colon abnormality, the existing psychosis, dementia praecox, must be a contributing factor, at least, in this abnormality.

The patients used in this study were felt to be clinically normal. They all ate well and lived a fairly regular institutional life. All were adequately nourished. Such factors as under or over-nourishment could definitely be eliminated. The amount of physical exercise was uniform throughout the group inasmuch as none were under nor overworked. Their routine life was not unlike that of the average man on the outside. The type of food was standardized and although any individual could have all he wished, it was controlled in that he must eat a maintenance diet and a balanced one. The musculature of the abdominal wall in the group was good in 44 cases and lax (poor) in 4 cases. It is relatively certain that none of these factors could have played a very important part in producing abnormalities in the tonus and emptying time of the colon. The body type was then studied in its relation to the colon tonus and emptying time in order to determine its effect. There were 14 cases with pyknic body habitus, 6 with athletic body habitus and 28 with asthenic body habitus. Of those with pyknic habitus 12 had abnormal colon emptying time and 10 abnormal colon tonus (in 2 cases it was decreased and in 8 increased). Of those with athletic habitus 6 had abnormal colon emptying time and 4 had abnormal colon tonus (in all 4 cases it was increased). Of those with asthenic habitus 16 had abnormal colon emptying time and 22 abnormal colon tonus (in 14 cases it was decreased and in 8 increased). It is clear that there is possibly some correlation between decreased emptying time of the colon and body habitus; *i.e.*, that the pyknic and athletic body types were encountered in far greater numbers where decreased colon emptying time was found than the asthenic body type. It is also clear that there is very little correlation between body habitus and colon tonus as a whole or between body habitus and increased colon tonus, but that where the tonus is decreased there will be more individuals with the asthenic habitus than with the pyknic and more in the pyknic habitus than with the athletic. Thus, whereas the colon tonus was decreased most frequently in association with the asthenic body habitus it was in this same habitus that the colon emptying time was least frequently found decreased. Work at the present is being continued to determine the accuracy of these findings in other psychotic groups. If the work which has been done by others on the relationship between the body habitus and psychosis may be accepted, the observations on the relationship existing between the body habitus *and* colon tonus and emptying time can easily be explained on the basis of the relationship existing between the psychosis and the body type, with the latter as a common finding. This has been pointed out by Henry (4) who attempted to show that the amount that the gastro-intestinal tonus and motility were effected by body habitus was relatively unimportant as compared with the variations accompanying schizophrenia.

(c) Dementia praecox, as it is conceived today, is a mental illness characterized by supposed marked deviations from the normal in personality, which deviations are emotional, overt, and intellectual. The changes in body chemistry or physiology found in an individual with dementia praecox are an expression of his psychosis and may not only reflect it but contribute to it.

A normal individual is usually considered as an entity in existence; as an individual reacting to his internal and external environment and expressing this reaction by thought, word or action. Upon occasion some emotional tension will bring about some physiological response which we are able to observe; such as, shaking in fear, crying in sorrow, striking in anger. These physiological responses are all the result of the emotion, certainly not the cause of it. Such responses can also be participated in by the gastro-intestinal tract, as when a reaction to an emotion occurs such as nausea and vomiting in disgust, constipation when worried, and sudden evacuation in moments of intense fear and excitement. These reactions are all logical and have repeatedly been explained by the equation—strong emotion reacts upon the autonomic nervous system which in turn elicits certain specified responses from the periphery. If this equation can be applied to a normal physiological response to a normal emotion there is no reason why it should not be applied to psychotic individuals thus: strong emotion with or without normal basis reacts upon an autonomic nervous system producing a physiological response which to the observer may appear incongruous but which, when all the facts about the train of events are known, is not incongruous but entirely logical and rational. If this is accepted as a reasonable working basis then it is entirely possible that the abnormalities of colon tonus and emptying time may have some rational, if not evident, basis. Thus the response of the colon to the emotion is an expression of

the psychosis and if the response assumes malignant proportions (such as retention of feces for days until such retention may produce physical symptoms) then the physiological response may contribute to the symptomatology of the psychosis.

(d) The colon tends to demonstrate that the personality of dementia praecox is not a uniform state but varies within the group as does the personality of any group of individuals. Thus the group designated as dementia praecox is not uniform but rather heterogenous.

If only the colon in dementia praecox is taken as an index or expression of the personality, or even as *the personality* as Dr. Adolf Meyer has considered it, it is at once obvious that the "colon personalities" of dementia praecox are not uniform. There is the colon that has a normal emptying time and then there are the colons with all degrees of delayed (indifferent) emptying times. Or there is the colon with decreased tonus, normal tonus, and increased tonus. Or if these two are considered as aspects of the "colon personality" then there are personalities which the colon expresses by decreased tonus, normal emptying time; decreased tonus, decreased emptying time; normal tonus, normal emptying time; normal tonus, decreased emptying time; increased tonus, normal emptying time; and increased tonus, decreased emptying time. This may appear to be an odd manner in which to describe a personality but is no more odd than to describe a personality in terms denoting inferiority, shyness, embarrassment, clumsiness, etc., all of which denote some physical or chemical state which is reflected by some more complex physiology. Again, if the personality may be described thusly and since all of these personality types were found in varying degrees and quantities in the studied dementia praecox group, the assumption is justified that either there are all types of personalities in a dementia praecox group or that the group of psychotic individuals called dementia praecox is a heterogenous one.

(e) The observed and objectively dominant emotions as expressed by the patient are not in every or many instances reflected by the colon. If the colon does express or reflect the personality of the individual then the observed and objectively dominant emotions of dementia praecox are misleading and probably a blind to the true personality.

In the group of individuals in this study their dominant emotional state was described as indifferent 35 cases, agitated 6 cases and tense, 7 cases. Where indifference was dominant 25.6 per cent of the cases had a normal colon tonus and 74.4 per cent an abnormal tonus (40 per cent decreased and 34.2 per cent increased); and in 28.5 per cent the emptying time was normal and in 71.5 per cent it was decreased. Where agitation was dominant the tonus was normal in 16.6 per cent of the cases and abnormal in 83.0 per cent (83.0 per cent increased); and in 33.3 per cent the emptying time was normal and in 66.6 per cent abnormal. Where tenseness was dominant the tonus was normal in 28.4 per cent of the cases and abnormal in 71.6 per cent (28.4 per cent decreased and 42.6 per cent increased); and in 28.5 per cent of the cases the colon emptying time was normal and in 71.5 per cent abnormal.

The correlation between the observed dominant emotional state and the tonus and emptying time of the colon was obviously very low. This was rather startling when one took into consideration the prevailing researches into this field. But possibly it can be explained. This low correlation may be due to (1) the actual existence of no relationship between emotions and gastro-intestinal response and vice versa; (2) the observed dominant emotional state not reflecting the true personality; or (3) the colon not reflecting the true personality.

The work of Cannon, Pavlov and a host of others would tend to indicate that there is a definite correlation between emotions and the gastro-intestinal physiology, and, moreover that the gastro-intestinal tract can to a certain extent be conditioned by the emotions. This would nullify (1).

In dementia praecox the objective psychotic state is frequently a mask or shell behind which, and thoroughly concealed, resides the true personality of the individual. It is unusual for a person with dementia praecox to exhibit his real personality, his real reactions to his total environment being something which he has withdrawn from reality and which belongs to him. This has been clinically demonstrated by many workers in this field and would tend to substantiate (2).

It is rather hard to conceive of the gastro-intestinal tract acting in a voluntary manner—of it taking the initiative with no stimulus whatsoever and setting the pace whereby false observations are liable to be made. It would appear that since the chemistry and physics of the gastro-intestinal tract are controlled by the autonomic nervous system that any functioning of the tract would be in response to some stimulus which would be controlled by this system. Since this system is not conscious, it is only reasonable to assume that it could not voluntarily be controlled; that the functions of this tract would be true reflections of stimuli whether they be emotional (conscious or unconscious), chemical or physical, overt or intellectual. If this all be true, and it is, then (3) is eliminated.

Thus, we find that (a) emotions do affect the gastro-intestinal tract and can condition it (b) these emotions can be conscious or unconscious (c) they can be completely concealed by superficial or false emotions which act as a blind giving the real emotions room for free play (d) the colon which is not subject to such concealment reflects the true emotional state of the individual.

(f) In the majority of cases of dementia praecox there is some imbalance of the autonomic nervous system as expressed by studies of the colon.

There is no question but that in the study presented herein, in the colons of individuals with dementia praecox there is a definite abnormality in the emptying time and/or tonus in a large number of cases. As is well known the normal functioning of the large bowel is dependent upon a normal balance existing between the sympathetic and parasympathetic nervous systems. When there is some imbalance, regardless of the precipitating factor or factors, there results

abnormal functioning of the colon. Since in many cases of dementia praecox there exists this abnormal functioning of the large bowel, it would appear unnecessary to ascribe it to any other mechanism than to the autonomic nervous system imbalance. The mechanism underlying this imbalance is in most all probability the emotional, overt and intellectual imbalance which constitutes the psychosis.

SUMMARY

A study of the emptying time and tonus of the colon in dementia praecox is presented.

It was demonstrated that in the majority of instances there was an abnormality in the functioning of the colon.

The possible mechanisms underlying this abnormality are discussed in detail.

Gastroscopy

Observation in 100 Cases*

By

EDWIN BOROS, M.D.†

NEW YORK, NEW YORK

THE introduction of gastroscopy into the field of diagnosis and research, marks one of the truly great advances in the realm of gastro-enterology. We have included the gastroscope as one of the important means at our disposal in this direction, and have during its employment, made certain observations which may be of interest not only to the clinician but the endoscopist as well.

To begin with, the choice of the patient for gastroscopy is not limited or confined to a certain type of individual or group of diseases to be considered. Mindful of the contraindications to the procedure which must at all times be respected, patients with symptoms referable to the gastro-intestinal tract are explored by means of this method after a detailed physical, chemical and roentgenologic examination has been undertaken. That the procedure of actual gastric inspection fills a definite need in the evaluation of problems dealing with alimentary affections, and offers promise of still further benefits as our perception and knowledge develop, can be surmised on the basis of past experiences and contributions in this difficult field.

Up to most recent times, the oft repeated references to technical difficulties and dangers to the patient, arising out of a gastroscopic examination was emphasized and served to retard rapid progress in the development of knowledge. The Wolf-Schindler apparatus, as previously suggested, has to a considerable degree solved many past objections, although the technique of gastroscopy has to be learned and practiced, often with perseverance and after disappointments. In short, there is no royal road to the desired goal, nor is this reflection intended to be construed as suggesting such colossal technical difficulties as may not be surmounted by the serious application of the prospective enthusiast.

*From the Bronx Hospital.
†Associate Gastro-enterologist.
Submitted December 15, 1935.

METHOD OF EXAMINATION

We begin the examination of the patient in the manner outlined by Schindler. It is insisted upon, that neither food nor drink be allowed for at least 12 hours prior to the examination. A reduction to a 6 hour interval between the intake of food and the instrumentation, resulted in the occurrence of a markedly congested mucous membrane of the entire stomach, so that it is advisable to maintain the longer fasting period, and thus minimize errors in interpretation. In one patient, with a marked gastric retention consequent on an organic obstruction at the pylorus, it was found necessary to lavage the stomach on the evening prior to the examination until the washings were completely clear. To this end, several gallons were required, yet despite every precaution towards obtaining the most favorable factors for visualization, the inspection of the gastric cavity was conducted under more than the usual difficulties as a result of the increased quantity of secretion inside of the organ. It is preferable not to lavage the stomach in any circumstances immediately prior to instrumentation so as to avoid marring the visual field.

In the matter of anaesthesia and general attitude and behavior of the patient, it is important to recognize, that time and patience are requisites for a proper technique. After the preliminary hypodermic injection of codeine gr. ½ and atropine sulphate gr. 1/100 fully ½ hour is allowed before the topical application of the anaesthetic to the throat is applied. This latter procedure likewise consumes another half hour. Hurrying at this stage does anything but help simplify the introduction of the gastroscope, and in a few instances where it was attempted, greater effort was required on the part of both the subject as well as the examiner.

Incidently, one cannot determine at the onset just how cooperative the patient is going to be, and how simple or difficult the procedure. The mere fact that the patient is scheduled for a gastroscopy is no assurance that a satisfactory gastric exploration will at all times be accomplished. Naturally, this factor is to be appraised in some degree in the light of the skill of the endocopist, but the fact must be recognized, that it is not possible to gastroscope every patient, and occasionally, even in the absence of the usually recognized contraindications of its employment, it may be considered inadvisable to proceed where undue nervousness, anxiety or lack of cooperation on the part of the patient are manifest. Nervousness, *per se*, is no contraindication to gastroscopy, but lack of cooperation is a definite drawback. We rely upon a detailed exposition of the procedure as we go along, and thus gain the confidence of the subject. This aptly called 'sermon' and its emphasis has been forcefully called to our attention by Jackson, and its observance is of paramount importance for a proper conduct of this procedure. A well trained assistant is absolutely indispensable. Only with the proper guidance of the head, can one be assured of a smooth performance at introduction of the instrument and proper visualization.

Not infrequently, we have found considerable resistance to the easy passage of the tube through the pharynx, as a result of marked tenseness or spasm of the crico-pharyngeal muscle, despite every exhortation towards relaxation or swallowing. However, it was seldom found necessary to give up the procedure except where fear or lack of cooperation permitted no other choice. In this connection, it might be well to remind one of the necessity for guiding the tube so that it does not get caught in the left pyriform sinus. It does not ever appear to find its way into the right pyriform sinus. We have not found any occasion where the larynx was entered although this is a possibility. It is important to remember that enforced pressure at any time during the procedure is dangerous, not only to the patient but to the instrument as well. At the present stage, the optical system of the gastroscope can readily be dislocated, resulting in damage to the lens system, but we have been up to the present, fortunate in this respect. It is at the 'diaphragmatic pinchcock' where occasional difficulties have been encountered. A spasm of the lower esophagus, occasioned by the presence of the tube has been met with, and has the effect of obstructing progress into the stomach, despite the administration of atropine and codeine prior to the examination. A speedy technique eliminates the frequency of such a phenomenon. Nevertheless, when present, it was found necessary to withdraw the instrument. By waiting for a few minutes, the resistance at the tip of the tube did not seem to give way, and blind forcing was deemed inadvisable. Visualization of the lower esophagus has been possible in some cases with the use of the retrograde gastroscopic tip. In three instances, the esophageal lumen was plainly illuminated up to the 20 cm. mark.

Once the technique of gastroscopy is acquired, the problem of orientation and recognition of the various mucosal changes and lesions of the gastric cavity has to be studied. It happens occasionally, that with the instrument *in situ*, the field is not illuminated. Here considerable patience and practice are required to establish a visual field, more particularly, one that includes the pylorus. The introduction of small quantities of air is required at this point, or else the instrument must be withdrawn somewhat, until the darkness disappears. Either of these procedures requires great care. A large quantity of air will tend to force the pylorus upwards out of line of the visual field and thus escape detection, or else in the attempt at withdrawal of the gastroscope, one fails in his visualization of the pylorus. The proper introduction of air can be learned only with experience. We have not encountered any ill-effects subsequent to the forceful injection of air into the gastric cavity, although such would not be advised where an ulcer of the stomach is suspected. Increased amounts of air have the tendency to flatten out the rugae, and every now and then the excess amounts are expelled by the patient during the examination. I have heard of one instance where perforation of the stomach, with air in the peritoneal cavity was noted and ascribed to the excessive introduction of air in a recent gastroscopy performed by one of my colleagues.

Of the one hundred case reports studied, the examinations in six of these were unsuccessful, partly because of the lack of cooperation on the part of the subject, and in two instances because of a generally unsatisfactory vision of the interior of the stomach subsequent to the successful introduction of the gastroscope.

COMMENT

The cases considered, offer interesting as well as instructive information with respect to certain phases and concepts of gastric disease or local expressions of general disease, in a manner which casts light on some of the darker and yet unexplained phenomena encountered in practice. A detailed analysis of the more salient observations is not contemplated within the limits of this paper. It is observed, generally, that the quantity of gastric juice as measured by the test breakfast, bears no relationship to the occurrence of inflammatory manifestations of the gastric mucosa. In all of our recordings, the routine use of the Ehrmann alcohol meal was employed in determining the degree of gastric acidity. We have been able to observe, that the mere presence or absence of acid in the gastric juice, does not of itself predicate the existence of inflammation, and by the same token, it was possible to demonstrate a definite gastric affection of the stomach wherein a perfectly normal chemical response to the stimulation of the test breakfast took place.

The association of a normal gastric mucosa in a patient suffering with duodenal ulcer has been noted by us in three cases in this series, and these findings, noted in the face of declarations of a 100% incidence of gastritis occurring in patients suffering with duodenal ulcer as noted by Konjetzny, Schminke, Orator, Puhl, etc., suggests the probability of considerable future controversy with respect to its meaning and significiance. Just what factors are responsible for this disparity in observation, which incidently, has been likewise confirmed by Schindler, still remains a problem. Are there such wide fluctuations in gastric healing as to explain these differences? It might be emphasized, that Konjetzny's observations were based on resection preparations mainly and therefore represented the end result of the medical phase of the life history of the ulcer, rather than the expression of intermediary forms and degrees of severity of patholo-

gical processes encountered during the course of an ailment.

With regard to the behavior of the stomach in diseases of the gall bladder, it has been demonstrated that variations in the degree of gastric acidity is not an unusual occurrence, (Ewald, Boas, Ohly, Duttmann, etc., and that subsequent to cholecystectomy, no alteration in this factor is brought about. (Ohly, Behm, Cohn, Rost, Popper, etc.). By endoscopic means, it has been possible to note marked gastric changes in diseases affecting the biliary passages, as well as perfectly normal stomachs. (Hohlweg, Korbsch, Gutzeit, Henning). Our experiences confirm these observations.

The not unusual occurrence of low or absent gastric acid values has been found to exist, not exceptionally, in the face of absolutely negative gastroscopic findings. In disturbances of the glands of internal secretion it has been shown that there may occur low gastric secretory levels. (R. Schmidt, H. Zondek, etc.). In Graves' disease it is not unusual to encounter an achylia gastrica. However, in a patient in my series, there was an absence of any affection of the inner lining of the stomach, which speaks for a sympathetic origin for the depressed secretion in the patient under discussion.

H. Quincke recorded the association of a complete gastric atrophy in pernicious anemia. This was subsequently confirmed by the work of Nothnagel, Lubarsch, Koch, Wallgren, Faber and others. In a series of 150 cases of pernicious anemia, Morawitz reported the presence of a total achylia in every one of them. However, occasional recognition of hydrochloric acid in this form of anemia was recorded by Naegeli, Cabot, Levine, and Ladd, Lenhartz, Strauss and others. In one instance I found no generalized atrophy, but areas of intervening healthy mucosa could be detected, in contrast to a different case, where complete gastric atrophy existed.

CONCLUSIONS

That the diagnosis of gastritis belongs entirely within the province of the gastroscope, is at the present time, generally accepted. (Gutzeit, Korbsch, Henning, Schindler, etc.). Notwithstanding the fact that clinical observation, the execution of a carefully conducted physical, chemical bacteriological and X-ray examination are absolute essentials for a proper concept and evaluation of a given case, one cannot gainsay but that gastroscopy's applicability extends into that realm where the diagnosis may be obscure and where further knowledge and investigation is endeavored.

Mesenteric Vascular Occlusion: Report of an Instance with Acute Venous Thrombosis Following Splenic Artery Embolism and Infarction*

By

ELMER MILCH, M.D.

and

GEORGE MASOTTI, M.D.

BUFFALO, NEW YORK

FEW disease entities in medicine make their appearance so dramatically, present so obscure a picture, and run so rapidly a fatal course in a large percentage of instances, as do the cases of mesenteric, vascular occlusion.

The term "mesenteric vascular occlusion" is to be preferred to "thrombosis" or "embolism," as it includes both of these conditions, and, therefore, it is less confusing unless one refers specifically to either a thrombosis or an embolism.

HISTORICAL DATA

The first case was reported by Tiedeman in 1843. Virchow, in 1847, was the first who described the pathology. In 1863, Kussmaul and Gerhardt made the first attempt to establish a definite clinical syndrome. From then until 1904 there is a paucity of literature concerning mesenteric occlusion, at which time Jackson, Porter and Quimby collected and carefully analyzed 214 cases from the literature and their own personal experience. In 1913, Trotter published his Cambridge monograph on "Embolism and Thrombosis of the Mesenteric Vessels" in which he summarized all the work done on the subject to that date. Since then the literature has become replete with summaries and case reports, perhaps the most comprehensive of which is that of Warren and Eberhard.

It is the purpose of the present contribution to review a few of the more salient features of venous and arterial mesenteric occlusion, and to report an instance of mesenteric, venous occlusion due to a comparatively rare combination of etiologic factors.

PATHOGENESIS

The pathologic changes produced by an occlusion of either the *arterial* or the *venous* mesenteric circulation are quite constant. The end result comprises a hemorrhagic infarction of the affected bowel. When the artery is occluded by either a thrombus or an embolus, the first change noted is a distinct edema associated with a leukocytic infiltration composed chiefly of mononuclear and polymorphonuclear leukocytes. As a result, the tissues become markedly swollen. Discrete capillary hemorrhages appear and the capillaries and venules distend with blood. Villi degenerate. Necrosis and gangrene constitute the terminal pathology.

The end result of *venous* mesenteric occlusion is essentially the same, only it is brought about in a different fashion. When the collateral venous circulation is not sufficient to cope with the occlusion, the blood remains in the venous capillaries. New blood is constantly being fed to these structures by the arteries, so that eventually the veins distend and become paralyzed. This leads to an extravasation of serum and blood between the intestinal coats and the production of a hemorrhagic infarct, accompanied by gangrene.

ANATOMICAL CONSIDERATIONS

The *superior mesenteric* artery arises from the anterior surface of the aorta about 1.25 cm. below the celiac artery; it supplies the entire small intestine from the duodenal-jejunal flexure to the ileo-cecal valve, cecum, ascending colon, and one-half of the transverse colon. It has numerous branches, each of which anastomoses with the other to form 3 or 4 tiers of "arcades." Where the most distal of these twigs enters the intestine a final anastomosis takes place. Likewise, the *inferior mesenteric* artery, which supplies the remainder of the large bowel to the pelvic colon, has many anastomoses. In addition, the *inferior phrenic artery* is linked with the upper jejunal, to the hepatic, gastro-duodenal, superior and inferior pancreatico-duodenal vessels. The *internal iliac* and inferior mesenteric arteries are linked through the internal pudic, inferior and middle hemorrhoidal arteries.

The *mesenteric venous circulation* has an even more pronounced and abundant collateral circulation. The chief vessels and their branches, which correspond to the arteries, practically have similar anastomoses. In addition, there exist numerous anastomoses between the portal and systemic circulation by means of small systems of tributary veins too numerous to detail.

EXPERIMENTAL CONSIDERATIONS

Since such a rich network of arterial and venous anastomoses is present, one naturally wonders why an occlusion should produce infarction in such a great number of instances. Numerous investigators have attempted to solve this problem. Among the outstanding of these workers are Conheim, Litten, Cohn, Bolognesi, and Reich. Their results do not agree in their entirety, but they do so on certain essential points.

If the *superior mesenteric artery* is ligated at its trunk, the affected portion of the intestine is immediately thrown into violent paroxysms or spasm, lasting 2 to 3 hours; such automatically increase the peripheral resistance, and prevent a dilatation of the capillaries, upon which the establishment of a collateral circulation is entirely dependent; an infarct follows. Very few cases do not react in the above fashion, and the collateral circulation may handle the situation, but

even that breaks down later in the patient's life when the original and primary etiologic factors are aggravated. A third possibility is that mesenteric occlusion may interfere with the circulation of the intestine only to the extent of destroying its function, but not doing so sufficiently to cause gangrene; in this fashion, a "functional" obstruction is produced.

If the occlusion is in a branch of the inferior mesenteric artery, whether or not an infarction will follow, is dependent entirely upon the size of the vessel and the amount of bowel which it nourishes.

In animals, ligation of the *superior mesenteric vein* is always associated with hemorrhagic infarction. However, in man, mesenteric venous occlusion definitely is a slower process. A great portion of the mesenteric venous circulation may be occluded before infarction results. Reich, after a careful analysis, concludes that infarction ensues only when the thrombus in the mesenteric vein extends so far into the smaller tributaries that it has reached the intestinal wall. In this manner, the clot extends into the mural "arcades," and, in so doing, prevents them from anastomosing with arcades of the adjacent free vessels, thence from emptying into the main veins above or below the superior level of the thrombosis.

INCIDENCE

The frequency with which the arterial system is involved as compared with the venous system varies according to the experiments of different investigators; both extremes are encountered. Most writers agree, however, that the incidence of arterial occlusion is greater than that of venous, in the ratio of 3:2.

The superior mesenteric artery is involved approximately 40 times more often than the inferior mesenteric artery. Three reasons have been advanced in an attempt to explain this preponderance: (1) the superior mesenteric artery has a diameter 3 times as great as that of the inferior mesenteric artery; (2) the superior mesenteric artery lies almost parallel with the aorta, whereas, the inferior mesenteric artery leaves the aorta at an angle of 45°; (3) because of its origin, the superior mesenteric artery has the first opportunity to intercept an embolus.

Primary occlusion of the superior mesenteric vein *alone* comparatively is an uncommon lesion, although there have been a few isolated instances recorded. Usually, the vein is involved terminally in a process descending from the portal vein or one of its tributaries. Thrombosis of the inferior mesenteric vein, *per se*, is of rare occurrence, and when present only occasionally results in infarction because of the elaborate collateral circulation for the relatively small area drained.

ETIOLOGY

The etiologic factors concerned in mesenteric occlusion vary. Infarction, as a result of closure of the arteries, may be due either to a thrombosis or to an embolus. Factors which predispose to thrombosis are arteriosclerosis and arteritis. Those which predispose to embolism are: (1) endocarditis, (2) cardiac parietal thrombi, (3) and possibly ulcerated atheromatous plaques (?) etc.

Mesenteric venous occlusion practically is always due to thrombosis. One case (Moloschin's) due to a retrograde embolism, has been reported. The occurrence of venous occlusion by embolism is so rare as to make the condition almost negligible. Here, again, constitutional diseases which predispose a patient to thrombosis may cause either primary closure of the mesenteric vein or terminal involvement in a descending thrombotic process. The causative agents of mesenteric venous occlusion are generally divided into four main groups:

A—Infectious: This group includes all cases in which there are infections in the region drained by the mesenteric veins; such permit penetration of the vein walls by bacteria, and the setting up of a local phlebitis, *e.g.*: appendicitis, pelvic abscess, severe enteritides, peritonitis, subdiaphragmatic abscess, perforated peptic ulcer.

B—Hematogenous: This group consists of the blood dyscrasias which so alter the constitution of the blood

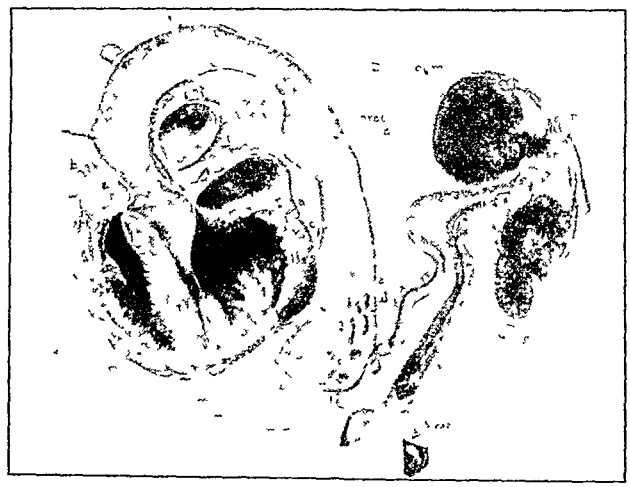

Fig. 2. Diagrammatic representation of coronary occlusion (a, b), parietal thrombi (c), thrombi in aorta (d), splenic artery embolus, infarction of spleen, and venous thrombosis.

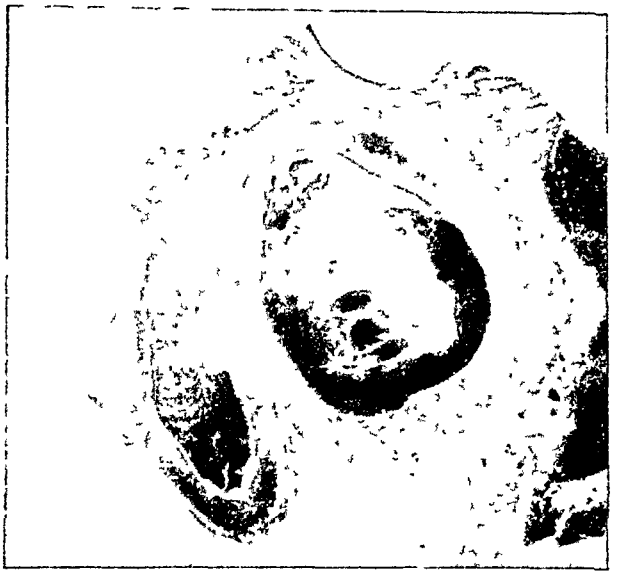

Fig. 3. Cross-section of splenic artery and vein showing embolus and thrombus in each respectively.

that there is a definite tendency to thrombus formation, *e.g.:* splenic anemias, polycythemia *vera.*

C—Traumatic: This group is comprised of those cases in which the thrombosis is the end-result of injury, *e.g.:* abdominal surgical procedures, tearing of the mesentery, rupture of a viscus.

D—Mechanical: This group, perhaps the largest, includes those cases which are due to occlusion of the veins by (1) regional neoplastic processes, (2) portal stasis caused by such entities as cirrhosis of liver, hepatitis, syphilis, cavernomatous transformation of the portal vein; (3) adhesions, (4) volvulus, (5) strangulated herniae.

PERSONAL EXPERIENCE

The Buffalo General Hospital is an institution serving both a private and ward clientele. It cares for medical and surgical cases and averages approximately 9,000 admissions per year not including those received in the Out-patient Department. Of these admissions about 58% are surgical cases.

During the years 1927-34, there were 72,409 admissions of which 44,502 were surgical patients. Mesenteric vascular occlusion was found in 17 cases The incidence of mesenteric occlusion, proven either by necropsy or by operation among the general admissions was .015%, and among the surgical admissions .025%. In the same time-period, there were 1395 autopsies; mesenteric occlusion comprised 0.6% of the necropsies. Of these, 40% were instances of arterial occlusion and 60% were those of venous occlusion.

The average age incidence of these cases was 44 years, the youngest was 20 years, and the oldest 66 years Peculiarly, in our series, males predominated in the ratio of 11-6; only in this respect did our statistical analysis exhibit a marked difference from instances recorded by other observers.

We were fortunate either in making the definite diagnosis of or in suspecting mesenteric vascular occlusion in 25% of the patients, but unfortunate in experiencing a mortality rate of 100%, whether or not the subjects came to surgery. We were unfortunate again in having no instances of spontaneous recovery such as has been reported repeatedly in the literature.

The average time duration from the onset of symptoms to hospital admission was slightly more than 54 hours. Of course, we had no way of determining how long the occlusion had been present before signs and symptoms developed.

Post-mortem observations: Of the 17 cases, 10 came to necropsy. The following is a list of the *causes of the mesenteric vascular occlusion:* arterial occlusion was caused twice by emboli originating in an aortic and mitral endocarditis; twice by emboli from mural thrombi in a fibrillating heart; and once by thrombosis associated with marked atherosclerotic changes in the wall of the superior mesenteric artery; venous occlusion was caused three times by thrombophlebitis associated with appendicitis; once subsequent to splenectomy, and once following splenic infarction, brought about by emboli carried into the splenic artery from cardiac mural thrombi. (This last case will be described in detail later).

CLINICAL PICTURE

The clinical picture essentially is alike for both arterial and venous occlusion. There are two accepted syndromes: one, *acute;* and two, *chronic* or "phlegmatic." The latter form rarely is diagnosed clinically, exhibits very vague and obscure gastro-intestinal symptoms, which to the clinician often are meaningless. It is usually associated with venous occlusion and is only recognized *in vivo,* as a rule, when, violently and dramatically, it assumes the characteristics of the acute group.

Pain is the outstanding symptom. Generally it comes on suddenly and, more often than not, without any premonitory symptoms. It is severe, lancinating, and colicky in nature at the start. It may be generalized throughout the abdomen, but frequently is localized in one area. The patient verges on complete collapse. The pulse is rapid, thready and weak. The lips are cyanotic and the extremities cold and clammy. Initially, temperature is subnormal. The patient is restless and apprehensive; he seems to realize as if by a sixth sense, that he is desperately ill. The pain may disappear only to return repeatedly in the same form; the time interval between attacks becomes less and less.

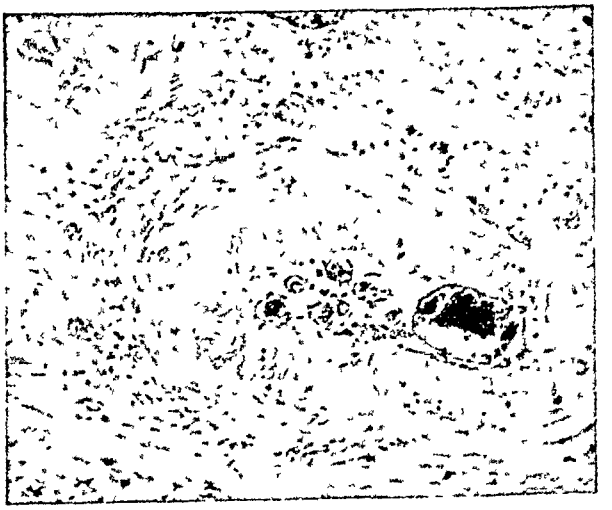

Fig. 4 Splenic artery with recanalization.

Fig. 5. Jejunum showing hemorrhagic infarction with recent thrombi in the submucosal veins.

Emesis is a quite constant sign, and at this stage is reflex. *Constipation* or *diarrhea*, or both, may occur. *Melena*, when present, indicates that some mechanism is causing serious interference with the intestinal blood supply.

At this stage, there are few *physical findings*. Generalized or localized tenderness may exist; as yet there has occurred no irritation of the parietal peritoneum and consequently there is no muscle spasm.

Very early in the clinical episode, however, a marked leucocytosis customarily is found, associated with a distinct increase in the percentage of polymorphonuclear leukocytes.

If the patient survives the initial shock, and mesenteric occlusion is neither diagnosed nor suspected, the picture rapidly progresses to one of intestinal obstruction. The pain loses its rhythmic character and becomes a constant, persistant, dull ache of peritonitis. The emesis is no longer reflex but obstructive. If bloody, it indicates a high circulatory interference involving the jejunum; it is a grave prognostic omen. At this stage, the course rapidly assumes the terminal features of intestinal obstruction and peritonitis.

Kussmaul and Gerhardt, in 1863, advanced certain postulates to aid the clinician in suspecting or actually making the pre-operative or ante-mortem diagnosis of mesenteric occlusion. These postulates are still held good:

(1)—The source for an embolus or thrombus, (2)—The presence of embolic phenomena elsewhere in the body, (3)—Melena, not to be accounted for by a primary intestinal lesion, (4)—Acute, severe, lancinating, colicky, abdominal pain, (5)—Subnormal temperature at the onset.

The *differential diagnosis* must consider the possible presence of any acute, abdominal surgical lesion; reference well may be made to the statement of Ross, in which he claims that in the majority of cases mesenteric occlusion is not a question of wrong diagnosis, but one of no diagnosis.

TREATMENT

If mesenteric vascular occlusion is to be treated intelligently it has to be diagnosed or suspected very soon after the onset of symptoms. The treatment is the same as that for any form of intestinal obstruction, *i.e.* early surgery. One point need be emphasized. No matter how critical the patient's condition appears unless the infarcted portion of bowel is removed it will terminate fatally in almost 100% of cases.

CASE REPORT

First admission 1/8/35. Service of Doctors Wright and Regan. The patient was a white male, aged 53 years, whose occupation was that of a waiter.

For the past eight months he had noticed a bluish discoloration of both feet, and that they had become progressively colder to touch. Two months before the patient inadvertently dropped a dresser drawer across the metatarsals of the left foot, and, subsequently, he was troubled with severe pain in the left foot, most marked in the fourth toe. The toe gradually assumed a darker hue and the pain became more severe. The patient consulted his personal physician, who administered a course of foreign protein therapy (typhoid vaccine); this aggravated the symptoms. On admission to our hospital the patient was unable to walk, and the foot had to be held below the level of the bed for the greatest degree of comfort.

The past history revealed a gastric hemorrhage four years ago, the etiology of which could not be ascertained and a bilateral thrombophlebitis of both lower extremities subsequent to a motor accident two years ago.

Examination: The temperature, pulse and respirations were normal. The heart was enlarged definitely to the left, and no murmurs were present. Both feet were cold and cyanotic. The fourth toe of the left foot exhibited dry gangrene. The dorsalis pedis and posterior tibial arteries were not palpable on the left leg and were barely palpable on the right.

The urine had a specific gravity of 1018, its analysis negative. The r. b. c. was 4,000,000; Hg. 80(S); color index 1. The w. b. c. was 12,500; the differential count was normal. The blood sugar was 115 mgms. and blood urea N. 11 mgms. The Kahn and Wassermann tests were negative with all antigens. Radiographic examination of the lower extremities did not reveal any evidence of calcification in the arteries.

On 1/14/35 Doctor Regan crushed the posterior tibial and superficial peroneal nerves for the sole purpose of relieving the excruciating pain. On 1/24/35 he amputated the gangrenous toe, and shortly thereafter Buerger's exercises were inaugurated. On 1/30/35 hyperemia and slight edema developed along the course of the right saphenous vein. This responded nicely to conservative treatment. On 3/3/35 the patient was discharged to the care of his private physician. All of the operative wounds had healed nicely, and there had been no pain since the nerves were crushed.

Second admission, 9/18/35—service of Doctor N. G. Russell. Since his discharge the patient had been in excellent health until approximately 4 weeks prior to readmission; at this time he began to experience constant, persistent, dull, gnawing pain, just to the left of the epigastrium; this pain was not relieved by food or alkali. On 9/7/35, about one hour after eating his evening meal, he experienced a sudden, severe, excruciating and lancinating pain in the abdomen and he collapsed. About 2 a.m. he vomited what was described as coffee-ground material. After vomiting he drank some water, but immediately regurgiated the liquid plus some blood clots. About this time he developed a bloody diarrhea. The patient required repeated ½ grain

doses of morphine for relief, and the morning of 9/8/35 was admitted to the hospital; this was approximately 15 hours after the onset of symptoms.

Temperature 100(R), pulse 140, Respirations 12.

Physical examination revealed a desperately ill patient, apprehensive, cold, clammy, and with a peculiar ashen gray cyanosis about the face. There were a few crackling rales at the bases of both lungs. The heart was very rapid, tones distant, regular; there were no murmurs. Blood pressure 104/86, (pulse pressure 18!) The abdomen was not distended, but there was marked tenderness in the epigastrium and in the left flank. At no time could muscle spasm or a mass be demonstrated. Rectal examination revealed no abnormalities.

The urine had a specific gravity of 1020; albumen and glucose were 1-plus, and the sediment revealed many w. b. cells and an occasional r. b. cell. The r. b. cell count was 5,000,000, Hg. 100% (T); the w.b.c. was 35,000, polys 93%. The blood sugar was 248 mgms.. and urea N. 41 mgms. per 100 c.c. The stool exhibited 4-plus occult blood, and was watery and grossly bloody.

The electrocardiogram was interpreted as showing no change significant of recent coronary occlusion, but definite changes referable to an old infarction.

The patient failed rapidly in spite of all the supportive therapeutic measures instituted. Death occurred 26 hours subsequent to hospital admission.

The clinical diagnosis rested between a perforating and penetrating ulcer involving the pancreas and a mesenteric thrombosis.

Necropsy findings: The autopsy was performed 30 minutes after death. The pertinent anatomical features were — total occlusion of the circumflexing branch of the left coronary artery by a completely obliterative thrombosis; marked narrowing of the oblique descending branch in the anterior wall of the left ventricle; moderate atherosclerosis of the descending anterior branch of the left coronary artery without complete obstruction; very extensive fibrous myomalacia of the left ventricle, most marked in the posterior wall, with several polypoid vegetations attached to the fibrous endocardium; distinct diffuse fibrosis of the anterior wall decreasing in severity towards the septum; so-called "diffuse wall aneurysm" of the left ventricle, especially at the anterior and posterior walls from fibrous organization of myomalacious infarcts. (Rokitansky aneurysm); distinctly dilated left ventricle; marked atherosclerosis of the lower thoracic and entire abdominal aorta; localized recent parietal thrombi at the lower end of the thoracic aorta; multiple old infarctions of the spleen, with extensive adhesions to the diaphragm; considerable atherosclerosis of the splenic artery (aneurysm serpentinum).

There were *complete occlusion of the distal portion of the splenic artery by thromb-embolus;* firm adhesions between splenic artery and splenic vein near and at the hilus; *obliteration of the distal portion of the splenic vein by an organized thrombus; more recent ascending thrombosis in the proximal part of the splenic vein; entirely recent massive thrombosis of the mesenteric vein; portal vein, and colic vein, with recent hemorrhagic infarction of the upper jejunum, and hemorrhagic necrosis of its entire wall;* very severe enterorrhagia; no hemorrhagic necrosis in lower jejunum and ileum; approximately 1,000 c.c. of thin blood tinged fluid in the peritoneal cavity.

The involved portion of the intestine measured 65 cm. and was markedly distended. The serosa presented a dusky bluish red hue, and was covered with flakes of fibrin. The bowel wall felt soggy, edematous, and was studded with many petechial hemorrhages. The normal sheen and lustre of the peritoneal coat had entirely disappeared. There were a few focal areas of necrosis, varying in size from pinhead to split pea. The arterial mesenteric system exhibited no gross involvement. The thrombosis of the portal and mesenteric veins was very recent, dark red in color and only slightly adherent to the intima. It extended into the smallest of the mural arcades on the intestinal wall. The thrombosis of the splenic vein felt firm, was grayish red in color, completely adherent to the intima, and extended directly into a large infarcted area located in the hilus of the spleen.

On serial sagittal section of the spleen, an old, firm, wedge shaped, infarct was found measuring 3 x 2.5 x 0.5 cm. beginning in the hilus of the spleen, and extending through the entire splenic structure, to the serosa on the opposite side. The apex of the wedge was situated in the hilus, and the fan shaped portion at the periphery. The splenic artery and vein, together with their associated thrombi could be traced directly into the apex of the infarcted portion of the spleen.

Splenic artery: Histologically, the intima for the most part was of average thickness. In certain localized areas, however, it was markedly thickened, apparently due to fibrous tissue. The internal elastic membrane had undergone reduplication. The tunica media was of normal width. The adventitia was composed of fibrous tissue, and in sections examined was not adherent to the vein. It contained a few scattered lymphocytes. The lumen was practically entirely filled with thromb-embolus composed chiefly of fibrin, red blood cells, and a very few leukocytes. In one area it was adherent to the intima, and here the endothelium was deficient. The thromb-embolus exhibited a focal area of organization. No evidence of a tuberculous or leutic arteritis could be demonstrated.

Spleen: Typical anemic infarction with beginning organization and reactive inflammation.

Splenic vein: The vein was completely occluded by an adherent thrombus made up of fibrin, red blood cells, and leukocytes. The wall appeared not remarkable. There was no evidence of a phlebitis.

Intestine: Practically complete necrosis of the mucosa and submucosa was present with small isolated areas of desquamation. The mucosal and submucosal vessels were markedly injected. Distinct recent hemorrhages were visible in the mucosa and submucosa. Submucosal veins showed recent thrombi, composed of fibrin, red cells, and leukocytes. Surrounding the veins was a distinct leukocytic infiltration. The entire picture was that of hemorrhagic necrosis with recent venous thrombosis.

SUMMARY

A case of mesenteric venous occlusion subsequent to infarction of the spleen is reported.

This case seems worthy of recording, not alone because of the symptomatology, but because of the sequence of etiologic factors concerned in the production of the pathologic lesions which were demonstrated post-mortem. Two sources manifest themselves as a possible origin of the thromb-embolus demonstrated in the splenic artery with the production of an anemic infarct located at the hilus of the spleen. (1), the polypoid vegetations found at autopsy clinging to the fibrous endocardium, and (2), the parietal thrombi situated in the lower third of the thoracic aorta. We feel that based merely on the incidence of occurrence, the most likely site of the two was in the heart. Since it is a proven fact that infarction of any tissue will produce thrombosis in the veins and the splenic vein was proved both grossly and histologically, to have its origin in the infarcted area, it is proper to assume that the original embolus causing the splenic infarct also was indirectly the cause of the thrombosis in the splenic vein. Also we feel that the terminal, mesenteric, venous occlusion definitely was a descending thrombotic process of some duration, as evidenced by

the gross and histologic appearance of the thrombus *in different areas of the vein.*

Bacterial stains (Gram and methylene blue), did not reveal the presence of any organisms in either the splenic artery or vein. Careful macroscopic and microscopic studies for a specific arteritis or phlebitis (tuberculous or syphilitic) as the causative agents in the production of the thrombosis were negative. As far as we are able to determine the splenic vein thrombosis was not due to adhesions between the artery and vein which may have formed after the throm-embolus occurred in the splenic artery.

A careful search of the literature revealed many cases of mesenteric, vascular occlusion, with incidental findings of infarctions in the spleen, or splenic vein thrombosis with a subsequent descending thrombosis of the mesenteric vein. However, the only case which we discovered in which mesenteric occlusion is a direct result of a splenic infarction, was one reported by L. T. Webster in 1921. This was a 45 year old man, who had a penetrating ulcer of the stomach with perforation into the splenic artery with a resultant thrombosis of this artery followed by massive infarction of the spleen, and terminally, a complete descending thrombosis of the portal system initiated in the splenic vein. We were unable to find record of any proved report in which the thrombosis of the splenic vein was due to a splenic infarction having as its source a thrombo-embolus originating in the heart, and lodging in the splenic artery.

SECTION II—*Experimental Physiology*

An Investigation into the Production of a Proteolytic Ferment in the Duodenum which will Increase the Anti-anemic Efficacy of Liver; Its Relationship to the Cause of Pernicious Anemia*

By

GARNETT CHENEY, M.D.

SAN FRANCISCO, CALIFORNIA

THE theory that pernicious anemia is due to the absence in the stomach of an intrinsic gastric factor, probably a proteolytic ferment, has received wide acceptance, but has seemed inadequate to the minds of a number of investigators (1, 2, 3, 4). The experiments herein described by the author apparently demonstrate the presence of this factor or ferment in the duodenal mucosa in a concentration equal to or greater than in the gastric mucosa. Proof of its presence in the small intestine would greatly alter the present concept of the etiological factors contributing to the cause of macrocytic hyperchromic anemias.

A vast amount of recent experimental work has led to the following explanation for the development of pernicious anemia, which has been widely accepted despite the recent report of Greenspon (5) to the contrary. Briefly, certain elements of the diet, notably muscle and organ tissue, supply a source of material which can normally be digested in the stomach to produce a substance necessary for the maturation of red blood corpuscles. Castle has called this part of the diet the extrinsic factor. He has named the digesting agent or unknown proteolytic ferment the intrinsic gastric factor. The substance produced by the interaction of these two factors may be termed an anti-anemic substance or maturation substance. The extrinsic factor is contained in most meats which are injested, particularly beef muscle, and in yeast preparations. Liver is an extremely rich source of this factor. The intrinsic factor has heretofore only been demonstrated in the gastric juice and the gastric mucosa. It is characteristically absent in pernicious anemia, or greatly diminished in amount (6). Consequently the necessary maturation substance is not formed and anemia results. However, this maturation substance

*From the Department of Medicine, Stanford University Medical School.

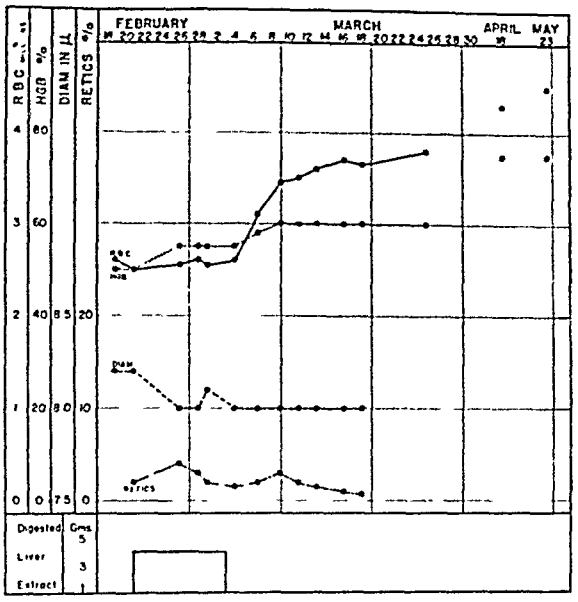

Fig. 1. Improvement of the anemia in Case II following the daily administration of one vial of liver extract No. 343 which had been incubated with 0.5 grams of duodenal mucosa.

is present in large amounts in liver, stomach and other organs, so that the oral or parenteral administration of these tissues or their extracts is highly effective in the treatment of pernicious anemia.

According to this theory anemia may come about in one of at least four ways. First, a diet deficient in the extrinsic factor will cause a macrocytic hyperchromic anemia as described in India (7), or as has been experimentally produced in pigs (8). Second, spontaneous absence of the intrinsic factor in the stomach will cause pernicious anemia; this is Castle's theory, but it is well recognized that if the source of the intrinsic factor is removed by gastrectomy in either man or experimental animals pernicious anemia does not develop except in a few very rare instances in man. Third, even if the maturation substance is present in the gastro-intestinal tract in adequate amounts it may not be absorbed and this is what occurs in severe dysenteries or possibly in sprue. Fourth, this maturation substance may be absorbed from the gastro-intestinal tract, but may not be utilized by the hematopoetic system. We are concerned here with only the second possibility, namely the absence of the intrinsic gastric factor. If this were the basic cause of pernicious anemia it is hard to see why spontaneous remissions occur and why after a remission has been induced a patient may not relapse for a year or more without any further treatment. Even more difficult to explain is the fact that gastrectomy does not ordinarily produce hyperchromic anemia, and that if it does the anemia does not appear until years after the operation.

In 1933, Kühnau (9) carried out a number of feeding experiments which suggested that the intrinsic factor was present in the duodenal secretion. As he employed a mixture of gastric and duodenal contents his work is not very convincing. In 1930 the Author carried out a somewhat similar feeding experiment incubating an average of 50 c.c. of duodenal contents daily with the juice pressed from one pound of beef steak. No special precautions were taken to try and prevent gastric contents from diluting the duodenal fluid. This mixture was made just alkaline to litmus and kept at 37° C. for one hour. It was fed daily for five days to a woman with severe pernicious anemia. An astonishing clinical improvement occurred, and the R.B.C. count rose from 1,060,000 to 1,660,000 and the hemoglobin from 30% to 44% within one week. The reticulocytes rose from 0.5% to 14% on the seventh day. She felt so well she declined further treatment. Although this patient must have received some gastric as well as duodenal secretion, the amount of duodenal contents used was less than that ordinarily required for successful incubation when pure gastric contents is employed. This fact together with the very rapid improvement in this patient's condition indicate that a ferment of high digestive activity may be present in the duodenal contents.

In 1935, Meulengracht (10) showed very clearly that the duodenum contained the same anti-anemic substance as stomach and he thought from his careful microscopic studies of the pyloric and duodenal glands that the duodenal mucosa might secrete the intrinsic factor. To prove its presence or absence is not simple. The difficulties of procuring pure duodenal secretion are obvious. It was felt that the most ready approach to the problem was to test the digestive powers of the duodenal mucosa on liver or liver extract in the same way that the digestive power of stomach mucosa is tested. It is now well recognized that when liver is incubated with gastric juice or with gastric mucosa its potency as an anti-anemic agent is increased several fold, and this is explained by the action of the intrinsic factor of the stomach on the extrinsic factor in the liver producing much more of the anti-anemic substance than was contained in the liver before incubation (11, 12). Exactly this principle is used in the preparation of Extralin by the Eli Lilly Company, cutting down the necessary daily liver extract ration to about one-third of what had been required previously. Fouts, Helmer and Zerfas (13) emphasized the advantages of using a small amount of a standardized liver extract as the source of the extrinsic factor in-

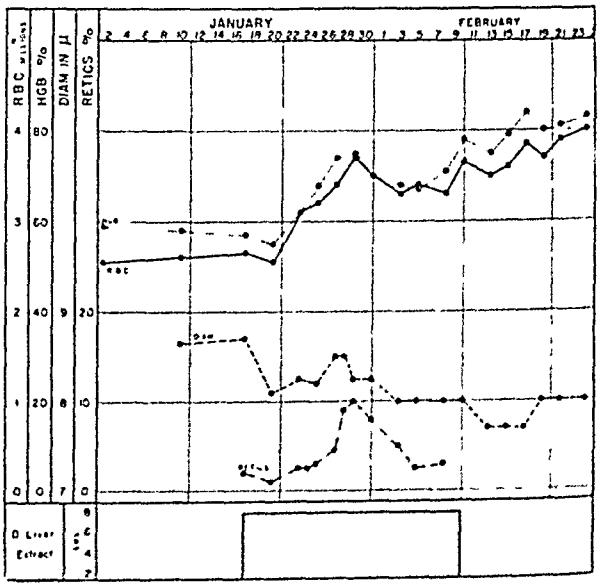

Fig. 2. Improvement of the anemia in Case VI coincident with duodenal liver extract therapy.

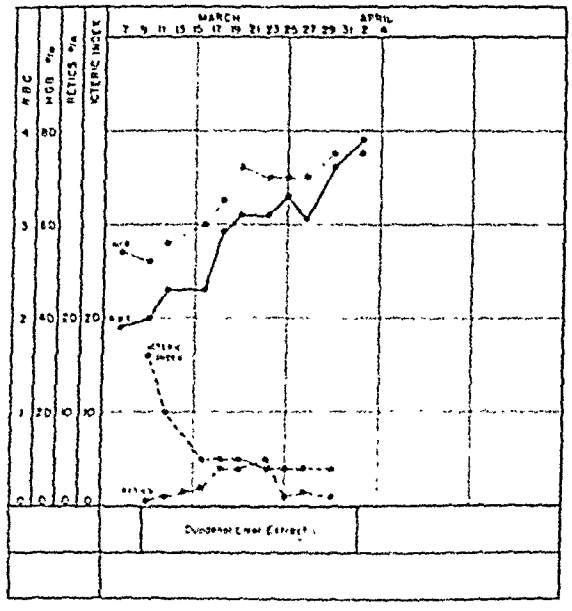

Fig. 3. Rapid improvement of the anemia and disappearance by hyperbilirubinemia in Case VII when treated with duodenal liver extract.

stead of beef muscle, Vegex or some other substance, the potency of which may vary to an unknown degree. They used the contents of one vial of Lilly's Liver Extract No. 343 which is the primary anemia fraction in powdered form derived from 100 Grams of whole liver. Its weight is approximately 4.5 Grams. The usual therapeutic dose of this extract is four to six vials daily when treating a patient with pronounced anemia, while one to two vials daily (4.5 to 9 Grams) are without beneficial effect. The presence of the intrinsic factor in a given amount of gastric juice or gastric mucosa may then be tested by incubation with one vial of the liver extract in solution and the resultant product fed daily for ten to twenty days to an anemia patient in relapse. If an average reticulocyte response and increase in red cells occur at a given erythrocyte level the intrinsic factor is present in sufficient amount for the quantity of gastric juice or mucosa used.

In the first group of the Author's feeding experiments two patients were treated. One vial of liver extract No. 343 was placed in 75 c.c. of 0.2% sodium bicarbonate solution to which 5 c.c. of a similar solution containing 0.5 Grams of human duodenal mucosa was added. This mucosa was secured by scraping normal duodenums obtained at autopsy after they had been resected and washed free of intestinal contents. This was carried out as soon after death as possible and the scraping put in the dilute alkaline solution in a beaker and kept in the ice box until ready for use, which was usually twenty-four hours but sometimes longer. As a rule the scrapings from two or more duodenums were prepared at the same time and mixed together. The duodenal mucosa liver extract mixture was incubated for one hour at 37°, and then placed in the ice box a few hours and administered cold. Two days doses were prepared simultaneously, the second dose being kept in the ice box over night.

In the second group of experiments the duodenal mucosa of the hog was incubated with liver in exactly the same manner as Extralin is prepared (12) except the duodenum was used instead of the stomach. I am indebted to the Eli Lilly Company for the preparation of this extract which contains approximately equal parts of powdered liver and mucosa. It was placed in capsules to facilitate its administration, each capsule containing approximately two-thirds of a gram of the powder.

FEEDING EXPERIMENTS. GROUP I

Case I. S. L. D., a 70 year old single male rapidly developed a severe anemia without gastro-intestinal or nervous system symptoms in the Summer of 1935. He had a moderate hypertension and had been under treatment for a diverticulum of the bladder with a low grade cystitis for several years. Two blood counts in 1932 were normal. His tongue showed no atrophy of the papillae. The spleen was not palpable. The deep reflexes and sensory discrimination over the lower extremeties were normal. The stool was negative. Gastric analysis showed achlorhydria to histamine. Complete gastro-intestinal X-ray studies were negative. Urinalysis was negative except for a few pus cells. The blood urea was 32 mgs. per 100 c.c. of blood. The R.B.C. count was 2,420,000 and the hemoglobin 43%. The average diameter of the erythrocytes was 8.1u. and the average volume was 115.2 cu.u. Although the color index was below one (0.9) a tentative diagnosis of pernicious anemia was made based on the macrocytic anemia with achlorhydria in an old man without any other obvious cause for an anemia. He was given 75 c.c. of a solution of one vial of Lilly's liver extract No. 343 incubated with 0.5 Grams of fresh duodenal mucosa daily for nine days; and again subsequently for a second period of fifteen days, although this period was interrupted for four days. The blood findings in relation to therapy are shown in Table I. As he was ambulatory and irregular in his attendance to the laboratory it was not possible to make as frequent and detailed blood studies as were desired.

Comment on the Results of Therapy. At the end of the first period of treatment the patient had gained 730,000 R.B.C. in nine days from an original level of 2,420,000 and the hemoglobin increase was 17%. Two weeks later without further treatment the total gain in R.B.C. for the twenty-three days was 1,210,000, and there was a further increase in hemoglobin of 5%. The blood count quickly fell and the color index rose to 1.2. During the second period of treatment the R.B.C. count rose 1,200,000 cells in three weeks, and the hemoglobin rose 7%. The average diameter of the cells was little altered. Four months later after taking liver extract and iron very irregularly the R.B.C. count was 4,210,000 and the hemoglobin 78%.

Case II. J. McD., a 62 year old single male indigent entered the hospital for the second time on Feb. 12, 1935, complaining of weakness. At his first entry a year previously he presented the classical picture of pernicious anemia with macrocytic hyperchromic anemia, hyperbilirubinemia, achlorhydria to histamine and neurological findings typical of subacute combined sclerosis of the spinal cord. He responded very satisfactorily to parenteral liver therapy with reticulocytosis and increase in red blood cells and hemoglobin. He received no maintenance liver therapy.

At the last entry the red cell count was 2,570,000, and the hemoglobin 50%. The average diameter of the erythrocytes was 8.2 u. and the average volume 128.4 cu.u. He was placed on the same form of treatment as was carried out in Case I, which he received for ten days. The effect on the blood picture is shown in Table I* and Fig. 1. He received no further antianemic treatment and five months later on July 10th was ambulatory and the red cell count was 4,550,000. The hemoglobin was 78% and the average diameter of the erythrocytes was 7.6 u.

*Omitted by the editor for sake of brevity.

Comment on the Results of Therapy. This patient's reticulocytes rose to 4% on the sixth day of treatment and gradually diminished during the next two weeks. The red cell count and hemoglobin per cent were stationary during the ten day period of treatment, but began to rise four days later. The number of red corpuscles then increased in twelve days from 2,590,000 to 3,690,000, a gain of 1,100,000 cells; and the hemoglobin rose 5%. The average diameter of the erythrocytes was diminished from 8.2 u. to 8.0 u. The blood count and hemoglobin per cent subsequently rose to normal, although no further liver extract was given.

FEEDING EXPERIMENTS. GROUP II

Case III. J. J. K., a 51 year old unemployed laborer was seen on Nov. 1, 1935, in a hospital outpatient clinic complaining of weakness and difficulty in walking. He had previously been in the County Hospital with severe pernicious anemia and moderately advanced subacute combined sclerosis of the spinal cord. He had shown a characteristic and rapid response to parenteral liver therapy and for some months after leaving the hospital had eaten some liver almost daily. He had taken no liver at all during the past six weeks. He walked with a spastic ataxic gait and had considerable pain in the left leg. He appeared ruddy but the R.B.C. count was only 3,570,000 although the hemoglobin was 75%. The average diameter of the erythrocytes was 8.1 u. and the average volume 129 cu.u. He was told to take four capsules of the duodenal liver extract three times a day and report regularly for blood counts. Unfortunately he appeared at the laboratory very irregularly, but the few blood counts made during the six and one-half weeks of treatment are recorded in Table II and show very well the marked improvement which occurred, which was also readily manifest clinically.

Comment on the Results of Therapy. This patient's red cell count was stationary at 3,600,000 cells for eleven days before treatment and for the first eleven days afterwards. During the next seventeen days it rose to 4,310,000, a gain of 710,000 cells. The hemoglobin also rose 10%. Some three weeks later and a week after treatment was stopped the red cell count was 5,310,000, a gain of another 1,000,000 cells, and the hemoglobin had reached 104%. Actually the patient gained 1,700,000 red cells and 29% hemoglobin in fifty-four days.

Case IV. Miss E. B., a 33 year old single school teacher, first came under medical observation in San Francisco on Dec. 9, 1935. Her home had previously been in the middle West where she had twice been extremely anemic in the last two years. Each time she improved rapidly on liver therapy. She was anemic again and also showed slight jaundice. Her tongue was smooth at the edges. A histamine gastric test meal revealed an achlorhydria. The R.B.C. count was 3,290,000 and the hemoglobin 80%. The color index was 1.2. The average diameter of the erythrocytes was 8.0 u., and a Price-Jones curve showed a shift to the right typical of pernicious anemia. The mean corpuscular volume of the erythrocytes was 124.6 cu.u. The icteric index was 15 units. She was treated with duodenal liver extract capsules receiving nine daily for three weeks. The favorable effect on the blood picture is shown in Table II.

TABLE I

Group 1. The effects of daily treatment of pernicious anemia with 4.5 gms. of liver extract incubated with 0.5 gms. of duodenal mucosa

Case No.	Date 1935	Day of Treatment	R.B.C. (million per cm.³)	Hgb. (%)	Average Diameter in u.

	9-18		3.88	70	7.9
	9-30		3.76	65	8.1

Comment on the Effect of Therapy. The red cell count increased by approximately 800,000 cells in less than three weeks reaching a normal level, and although the hemoglobin was already 80% it rose 5% higher. The average diameter of the erythrocytes diminished from 8.0 u. to 7.8 u. The icterus index fell from 15 units to 8 units. Her clinical improvement was striking.

Case V. T. F., a 56 year old Mexican housewife had been under hospital observation for six years on account of pernicious anemia, and all the hospital records were available for study. She had suffered six relapses before her present hospital entry. Two of these occurred while she was on a liver diet, and she always relapsed quite promptly when she ate no liver. On two occasions a liver diet containing 200 Grams of liver daily failed to produce a remission. On one occasion 2 c.c. of Lilly's Parenteral Liver extract injected daily for three weeks failed to produce any appreciable reticulocyte response or any increase

in red cells or in hemoglobin. Large doses of concentrated liver extract administered parenterally invariably instigated a typical and complete remission.

On Dec. 12, 1935, her anemia was severe. There were 1,250,000 R.B.C. and 24% hemoglobin. Therapy with duodenal liver extract capsules was started on Dec. 17, 1935. She received nine capsules daily but did not always swallow all of them. The relation of this treatment to the blood picture is shown in Table II.* It was continued for ten days only, when daily parenteral liver treatment was substituted as the patient's condition became very unsatisfactory. The blood count then began to improve and the reticulocyte count rose to 36% after the fifth injection of 10 c.c. of concentrated liver extract.

Comment on Results of Therapy. No definite response to the duodenal liver extract therapy was demonstrable in this short experiment, but it should be emphasized that this patient had previously failed to respond to oral liver therapy, and that the amount of duodenal liver extract she received by mouth was not large. However, it is noteworthy that during the ten days of the experiment that the icteric index fell from 15 units to 8 units, and that the subsequent rise in reticulocytes and number of R.B.C. may have been due in part to the oral therapy.

Case VI. E. P. T., a 53 year old housewife first came under observation in January, 1936, complaining of weakness. In the past eighteen months she had twice been in the County Hospital with anemia. She had responded slowly but definitely to liver therapy. Obesity and myocarditis were noted. At present her blood showed the characteristic findings of pernicious anemia. The R.B.C. count was 2,550,000 and the hemoglobin 59%. The color index was 1.2. The Price-Jones curve was typical of pernicious anemia with an average diameter of 8.65 u. The average volume of the erythrocytes was 130.8 cu.u. The icteric index was eleven units and the direct van den Bergh was negative. Gastric analysis revealed an achlorhydria to histamine. Gastro-intestinal X-rays showed nothing abnormal.

The blood count remained practically stationary for three weeks. Treatment was started on Jan. 17, consisting of four capsules of the duodenal liver extract t.i.d. The relationship of therapy to the blood picture is shown in Table II* and Fig. 2. Treatment was discontinued after twenty-three days, but the blood count was followed for two weeks longer.

Comments on the Results of Therapy. There was a gain of 1,150,000 R.B.C. and 20% hemoglobin by the 12th day of therapy, and the reticulocytes reached 10% on that day. Five weeks after the instigation of therapy the R.B.C. count had risen from 2,550,000 to 4,010,000 and the hemoglobin from 55% to 83%. The average diameter of the R.B.C. fell from 8.7 u. to 7.7 u. with a rise to 8.u. after the cessation of treatment. The icteric index had fallen from an initial 11 units to 7 units after three weeks. This rapid improvement of the blood picture to normal was accompanied by a marked clinical improvement. The patient was bed ridden at first, but was able to walk out of the hospital in six weeks.

Case VII. Mrs. D. S., a 54 year old Irish housewife was referred on March 7, 1936, by Dr. J. M. Meherin for the treatment of pernicious anemia. She complained of weakness, difficulty in walking and sore tongue. She was pale and slightly jaundiced. The tongue was atrophic. There were several abscessed teeth. The vibratory sense was lost over both lower extremeties. The red cell count was 1,900,000, the hemoglobin 54% and the color index 1.42. The average diameter of the erythrocytes was 8.6 u.

and the Price-Jones Curve showed a number of very large macrocytes. The average volume of the erythrocytes was 152.3 cu.u. The icteric index was 16 units. A gastric achlorhydria was reported by a physician who had seen her several years previously. She was forthwith placed on nine capsules of duodenal liver extract daily, and marked clinical improvement was soon evident. The rapid changes in the blood picture for the better are recorded in Table II* and Fig. 3.

The red cell count rose from just below two million to just below four million during twenty-four days of treatment. The hemoglobin per cent increased from 54% to 75%. The reticulocyte response reached a peak at 5.3% on the fourteenth day at the time there were three million red cells. The marked macrocytosis of the erythrocytes was reduced from a maximum of 8.9 u. to 8.2 u. The serum bilirubin fell to normal within the first week.

COMMENT ON THE EFFECT OF THERAPY

An analysis of the effects of treating these seven cases of pernicious anemia with small amounts of liver extract which had been incubated with duodenal mucosa reveals that six of the seven patients were benefited not only clinically, but also the blood picture improved markedly. In the one case recorded as a failure there seems to be sufficient reason aside from inadequate therapy why no improvement occurred. This is discussed in the protocol of Case V. In five of the cases there was an increase of one million or more red cells within three weeks and in four instances a gain of the same magnitude took place during a period of ten to twelve days. This improvement is all the more striking in that only one of these patients, Case VII, had an initial erythrocyte level under 2,500,000; as the less anemic patients ordinarily improve more slowly. In Case VII with an initial erythrocyte level of less than 2,000,000 red cells there was a rapid gain of approximately 2,000,000 cells in three and one-half weeks. In one instance, Case IV, there was a gain of only 800,000 red cells in three weeks, but this patient presented only a moderate diminution in the number of erythrocytes and the hemoglobin was normal. Actually her improvement was very satisfactory for the degree of anemia present.

The reticulocytes were studied in three of the six cases successfully treated and in each case there was an increase in their number to a maximum per cent corresponding to the expected average (14). In two of these patients, Cases VI and VII, there was a marked increase in the number of red cells previous to the time the highest per cent of reticulocytes occurred, and in two other patients Cases I and IV, a similar increase occurred before the time when the reticulated cells would ordinarily be expected to reach their peak. In each of these four patients a latent period of seven to ten days occurred following the initial rapid increase in the number of erythrocytes during which time no further increase in their number took place. A study of Tables I and II and Figs. 2 and 3 strongly suggests that an early complete maturation of erythrocytes developing in the bone marrow has preceded the appearance of large numbers of reticulocytes in the circulating blood. This is contrary to the usual sequence of events which takes place under standard forms of treatment. Its exact significance cannot be analyzed until further cases are studied.

On the whole the changes in the average diameter of the erythrocytes conform closely to those occurring under the usual liver and stomach therapy (15). The degree of macrocytosis was reduced in each instance except in that of Case V. The serum bilirubin concentration as measured by the icteric index was reduced to the normal range in each of the five cases in Group II including Case V. The icteric index was not studied in Group I. The rapid reduction in serum bilirubin which occurred in Case VII is shown graphically in Fig. 3 and indicates an excellent response to therapy (16).

The amount of duodenal liver extract used in treating these patients varied slightly, but was probably comparable with the amount of Extralin which would have been prescribed. It was always less than the amount of liver extract No. 343 which Minot (17) gives as the minimum which will produce a satisfactory response. In Group I the therapy differed from Group II in certain respects which are worthy of note. In this smaller group of two cases human duodenal mucosa was used which might contain a more concentrated amount of the unknown digestive enzyme than is present in the duodenum of the hog. This is suggested by the fact that the proportion of mucosa to liver used might be calculated as one to two hundred, as 0.5 Grams of mucosa were incubated with the liver extract derived from 100 Grams of whole liver. In the second group the proportion was about one to one, but incubation was carried out with fresh liver concentrate instead of just the dried primary anemia fraction. In the preparation of Extralin the proportion of hogs stomach used is also about one to one, but an adequate digestive reaction has not been reported if the proportion falls below one to twenty (18). This suggests the possibility that the unknown enzyme is at a higher concentration in the duodenal mucosa than in the stomach. Such an assumption is supported by the results obtained from feeding two patients, with hyperchromic macrocytic anemia, only three capsules (2 Grams) of duodenal liver extract daily. One of these patients suffered from a hepatitis, and the cause of the anemia was not determined in the other. A pronounced clinical and hematological improvement occurred in each. Also it must not be overlooked that successful therapy in all the patients treated with the duodenal liver extract might conceivably have been obtained from the presence of the liver extract alone, but this would seem most unlikely, as the incidence of satisfactory improvement following the administration of such small amounts of liver extract is extremely low. Further experiments are necessary positively to clarify this important point.

The presence of Castle's intrinsic "gastric" factor in the duodenum in a concentration equal to or greater than that in the stomach must alter the conception that the fundamental cause of pernicious anemia is a gastric defect. It seems probable that the presence or absence of this gastric factor would have no definite bearing on the development of pernicious anemia as long as there was an adequate production of the unknown ferment in the upper small intestine. This is best illustrated by the well known fact that total gastrectomy very rarely produces pernicious anemia, and then only in man. In the few cases in which it ap-

*Omitted by the editor for sake of brevity.

pears as a late sequel it may be due to gradually developing atrophy of the duodenal mucosa brought about by changes in the normal physiological functions in this region which such an operation might well incur. It is likely that in pernicious anemia there is ordinarily a combined gastro-duodenal defect, or as Meulengracht has termed it, an atrophy or inactivity of the pyloric gland (Brunner's glands) organ (10). The absence of pernicious anemia in many cases of gastric achylia with atrophy of the mucosa would also be explained. Whether an inability to produce this ferment in the duodenum could be compensated for by its production in the stomach cannot be decided at present, but is of the utmost interest in relation to sprue as in this disease the blood picture of typical pernicious anemia may develop with the presence of Castle's intrinsic factor in the stomach (19).

The results of the experiments recorded in this report naturally give rise to many other interesting questions concerning the etiology of all the macrocytic hyperchromic anemias which it would be premature to consider at present except on a theoretical basis. However, the possibility of this unknown ferment being related to enterokinase and its production in the jejunum or ileum as well as in the duodenum must be considered.

Histidine in Experimental Gastric Ulcer*

By

CHARLES WINDWER, M.D.

and

MILTON J. MATZNER, M.D.

BROOKLYN, NEW YORK

HISTIDINE hydrochloride was introduced by Weiss and Aaron (1) in 1933 for the treatment of peptic ulcer in man. In their investigation on dogs they used the Mann and Williamson (2) operation for the production of peptic ulcer, the principle of which is the diversion of alkaline duodenal, pancreatic and biliary secretions into the terminal ileum. As a result, protein digestion to the amino acid end stage, is interfered with. They concluded that deficiency of the essential amino acid, histidine, was responsible for the ulcer formation, since substitution therapy of histidine by injection prevented the occurrence of these lesions.

In this country, Volini and McLaughlin (3) produced gastric ulcers in rats by giving histamine parenterally and by enemata. In their report they state that these ulcers did not occur, when the animals were protected by previous injections of histidine.

Fontes and Bauer (4) repeated the experiment of Weiss and Aaron substituting oral administration of histidine for the parenteral method, and reported ulcer prevention in only 30% of the animals. They questioned whether the lack of histidine is the sole factor in the production of experimental ulcer.

Ivy (5) questions the basis of histidine-deficiency-theory. He believes "Weiss and Aaron did not 'run' their Exalto-Mann Williamson dogs long enough." Recently Sandweiss, Saltzstein and Glazer (6) performed the Mann-Williamson operation on twelve dogs in an attempt to repeat the experiment of Weiss and Aaron. They found that the animals developed ulcers even though they received daily histidine injections. Flood and Mullins (7) found that 6 out of 11 dogs re-

TABLE I

Group	Number of Rats	Feeding	Fluids	Injections	Results	Percentage
A	15	Fasting for two days Steenbock Bills Diet and fresh vegetables on third day.	2% pepsin and 0.3% HCl	Daily ½ c.c. Histidine	14 animals had ulcers	93%
B	15		2% pepsin and 0.3% HCl	None	14 animals had ulcers	93%
C	10		Water	Daily ½ c.c. Histidine	5 animals had ulcers	50%
D	20		Water	None	None	0

ceiving daily injections of histidine monohydrochloride after surgical duodenal drainage developed ulcers.

Our present investigation was undertaken to evaluate the efficacy of histidine monohydrochloride in the prevention of experimental gastric ulcer in the rat. Our previously described method of ulcer production (8, 9), based on the feeding of pepsin-hydrochloric acid, was employed in a somewhat modified form. A 2% solution of commercial pepsin (1:10,000 Parke, Davis & Co.) in 0.3% hydrochloric acid, instead of the originally described 20% solution was found equally effective.

EXPERIMENTAL

Sixty rats of the original Wistar strain, averaging four months in age were used in this experiment. The animals were divided into four groups as shown in Table I. The rats in all the groups were fasted for two days and fed the Steenbock Bills (10) stock diet with fresh lettuce and sliced carrots on the third day, in recurrent cycles for a period of sixteen days. Stoppered flasks containing a 2% solution of pepsin (1:10,000 Parke, Davis & Co.) and 0.3% hydrochloric acid were attached to the cages of groups A and B so that the animals could partake of these solutions ad lib. In groups C and D a continuous supply of water was available. In groups A and C the rats received daily injections of 0.5 c.c. of histidine monohydrochloride (Larostidin-Hoffman La Roche, Inc.) for nineteen days. Three of these injections were given prior to the onset of the experiment. To prevent leakage, the point of injection was sealed with collodion.

Fig. 1. Microscopic appearance of section of experimentally produced ulcer of the rat's stomach.

RESULTS

At autopsy, the pepsin hydrochloric acid group (A) that had received 19 daily injections of histidine revealed an incidence of about 93% of multiple gastric lesions of the pro-stomach. The incidence was equivalent to that of the pepsin hydrochloric acid group (B) that had received no histidine injections.

Autopsy findings in group (C) which received no pepsin hydrochloric acid mixture with daily injection of histidine disclosed that 5 of 10 rats (50%) had multiple gastric lesions. A control group (D) under a similar regime without histidine injections developed no gastric lesions.

The lesions had raised margins and umbilicated centers. The gross and microscopic picture (Fig. 1) of submucosal edema, cellular infiltration with varying degrees of desquamation and mucous membrane erosion in the rats which received histidine injections, was similar to that previously described (8, 9).

DISCUSSION

Histidine monohydrochloride is being subjected to universal trial in the treatment of peptic ulcer in man. Its use is based upon the histidine-deficiency-theory of Weiss and Aaron and on their reports in animal investigation.

The recent clinical investigations of Sandweiss, Martin, Flood and Mullins in the use of histidine in the therapy of peptic ulcer are not in full accord with the earlier favorable reports of foreign and American investigators. The original work of Weiss and Aaron on dogs has not been confirmed by other investigators. Recently, the value of histidine in prevention of experimental gastric ulcer in the dog has been questioned by Ivy (5) and Sandweiss, et al (6). The favorable reports of Volini and McLaughlin in preventing ex-

perimental gastric ulcer in the rat with histidine injections was not confirmed by our investigation. We found the incidence of gastric lesions identical in the groups on the ulcer producing regime, with and without histidine injections.

The high incidence (50%) of gastric lesions in group (C) in which no ulcer producing agent was employed appears to have followed the histidine injections. These ulcers may have been produced by a resultant histamine formation (11), since histidine may be converted by simple decarboxylation into histamine (12). Whether histidine parenterally administered in man, could through a similar conversion adversely influence a gastro-duodenal defect is a subject for future investigation.

SUMMARY

1. Experimental gastric ulcers in the rat were produced by our pepsin-hydrochloric acid method.

2. Daily injections of histidine monohydrochloride (Larostidin-Hoffman La Roche) were not effective in preventing experimental gastric ulcers.

3. A high incidence of gastric ulcers subsequent to injections of histidine were observed.

4. The conversion of histidine into histamine is suggested as a possible experimental ulcer producing mechanism.

Studies in Bowel Drainage

By

ANTON W. OELGOETZ, M.D.
PAUL A. OELGOETZ, B.A.
and
J. WITTEKIND, R.N.
COLUMBUS, OHIO

IF glucose is given in quantities in excess of 2 grams per hour, the blood sugar level rises and sugar appears in the urine. It has been believed that starch in any quantity is completely hydrolyzed (to sugar) and absorbed. However, when given in large quantities, starch does not effect the blood sugar level; does not appear as sugar in the urine; nor does it appear in the feces as starch or sugar.

It has been believed that the reason why starch does not act like sugar in the gastro-intestinal tract is because starch is often bound up in vegetable or fruit cells and is but slowly absorbed. But preliminary studies indicated to us that ingested starch has a twofold fate: part of it—that part which comes within the amylolytic threshold—is absorbed into the blood stream as sugar, while the remainder—the excess which cannot be hydrolyzed by the available enzymes during its passage through the upper bowel—passes to the colon, where it becomes the determining factor in the mechanism of normal bowel drainage.

Cannon long ago advanced the hypothesis that the motor mechanism of the bowel depends upon bulk: when the bowel is distended to the "just right" pressure, the intestinal muscles contract, thereby forcing onward the bowel contents. This observation was the basis of the former widespread use of bran and other indigestible bulky substances.

It is true that coarse, bulky roughage stimulates the motor mechanism of the bowel, but this stimulation results from the mechanical irritation caused by large unbroken particles contained in the feces. It is a common datum of observation that irritating roughage, bran for example, often overstimulates the bowel musculature, thereby producing constipation of the spastic type. This observation would seem to indicate that mere bulk or roughage is not the factor concerned in the mechanism of normal bowel drainage.

Schmidt long ago pointed out that there is no distinguishable difference between a "good drainage" stool and a "constipated" stool, although macroscopically and clinically they are as different as day from night. Schmidt believed that constipation resulted because the digestive enzymes did their work too well, so well that little food bulk remained to stimulate the bowel. Our observations indicate that mere bulk as such, is unimportant, but that the colloidal state in which the feces is dissociated is the determining factor which controls normal drainage. Because he believed, erroneously, that ingestion of different foods causes differences in feces, Schmidt introduced his test diet as a starting point, whereby feces of a uni-

Submitted January 30, 1936.

form composition, a normal stool, would be produced. Our observations indicate that normally, feces is always of a uniform composition, irrespective of the kinds of food ingested.

The composition of normal feces is as definite as is sodium chloride. If a bit of feces is rubbed up with distilled water and filtered, practically all will pass through the filter; only the large unbroken particles, such as spinach tissues and stems, seeds, etc., remain in the filter. Under the ultra-miscoscope the filtrate is seen to be a perfect colloidal suspension, *viz.*, small rounded, rod-shaped particles, approximately 25% of which are colon bacilli, some motile, most of them dead; and approximately 75% cellulose. Normally, in the unfiltered specimen, an occasional meat fiber is seen, very rarely an unbroken vegetable cell. In brief, normal feces produced from a general mixed diet is a perfect colloid; the larger vegetable tissues, seeds, skins, etc., are simply incorporations which are imbedded in the fecal colloid, much as the housewife sometimes incorporates fruits in a gelatine dessert. It is only when such are present in abnormally large quantities that they have any significance. It is the homogeneous, colloidal mass which constitutes normal feces.

Clinically, all normal feces naturally divides itself into two main types: the constipated stool, small in quantity, dark in color, formed, inspissated, expelled with difficulty; and the "good drainage" stool, large in quantity, light brown in color, soft in consistency and easily expelled. In practice we of course, find varying mixtures of these two types, and the degree of drainage depends directly upon which type prevails. The only essential difference between the two types is in the contained water. The good drainage type contains approximately 70% water, while the constipated type contains but 30% water. The water in both instances is held in chemical combination with the colloidal particles; it is never normally present as free water.

Fecal colloids (as well as other colloids) take on water because of a peculiar property known as imbibition, *i.e.*, the power of taking on water without forming liquid solutions. The factors which control the quantity of water which will be taken on by a colloid are the pH of the medium in which a colloid is suspended, and the iso-electric point of the individual colloid. The greater the difference between the pH of the suspending medium and the iso-electric point of the colloid, the greater the intake of water of imbibition, and hence the more thorough the drainage.

If feces of any type is rubbed up with distilled water, it will be found to have an iso-electric point of approximately 4.5. If the pH of a good drainage stool is determined, it will be found in the neighborhood of 7.2. The good drainage type of stool therefore shows a difference between the iso-electric point and the pH of the specimen of approximately 3, on the acid side, which accounts for the intake of two-thirds more water of imbibition. On the other hand, the pH of the constipated type of stool will be found to approximate the iso-electric point. When the iso-electric point and the pH of a specimen are identical, imbibition does not take place, and it is this lack of water of imbibition which produces the hard, formed, constipated stool. In practice we meet with mixtures of these two types, the pH ranging all the way from 7.2 to 4.5 and the degree of drainage (or constipation) varying as the difference between the pH and the iso-electric point.

pH is a symbol which indicates the concentration of H ions or active acidity in a solution or colloidal suspension, while the iso-electric point is that pH at which colloidal particles are electrically neutral or inactive. The pH of feces is determined by rubbing up a weighed quantity of feces in distilled water and filtering. The pH of the filtrate is electrically determined.

The iso-electric point of feces is determined by making a suspension of feces in solutions of different known pH values. A small quantity of the different suspensions is placed in a concave slide and the positive and negative poles from a high voltage battery are dipped into the suspension. The procedure is carried out under the low power microscope. When the circuit is closed the fecal particles can be seen to rush across the field to the positive pole, indicating that fecal colloids carry a negative electrical charge. When the pH of the suspending medium and the iso-electric point of the colloid are identical, the particles do not migrate when the circuit is closed.

A determination of pH and the iso-electric point of feces requires delicate and expensive apparatus, which, for practical purposes, is unnecessary. Clinically, the degree of drainage and the type of feces can easily be determined by placing a weighed quantity of feces in a Petric dish and drying in the warm air incubator. A "good drainage" stool contains approximately 70% water, while the constipated stool contains approximately 30% water. The experienced clinician however, can tell at a glance the degree of drainage by noting the color, consistency and quantity of stool.

Inasmuch as the iso-electric point of all feces is approximately 4.5, the practical application of the above observation resolves itself into how to control the pH of the feces. Observation has taught us that this can be done by the administration of large quantities of starch — quantities in excess of the pancreatic threshold, so that all of the starch cannot be hydrolyzed during its passage through the upper bowel. If more starch is taken than can be hydrolyzed by the available amylase, the excess passes to the colon where it meets with bacteria of the acid forming series. As a result of the action of these bacteria upon the starch and sugar, lactic and other acids in large quantities are formed. It is these acids, arising from colon carbohydrates, which determined the pH of the feces.

Practically, normal drainage can be quickly established by having the patient include in the regular diet a large helping (the more the merrier!) of any starch. The stool produced in this manner (which we prefer to call the "good drainage" stool or carbohydrate stool) is large in quantity, light brown in color, soft in consistency, results in but one daily evacuation, can be recognized at a glance, and leaves the patient with a delightful sense of completeness and thoroughness.

It is of course, presumed that the patient has previously been examined so as to preclude all pathological conditions which interfere with or prevent normal drainage. Likewise, the doctor should himself "see" the stool. Patients have many peculiar ideas concerning bowel drainage. They should be informed that

good drainage depends, not upon the number of daily evacuations, but upon the thoroughness of drainage. Many patients will report failure because the bowels have moved but once in 24 hours, while they believe that two or more evacuations are necessary; or because the quantity, in their estimation, is not sufficient; or because the stool is not watery and expelled with explosive force as following a cathartic.

CONCLUSIONS

1. The mechanism of normal bowel drainage depends upon the maintenance of a difference, on the acid side, between the pH and the iso-electric point of the feces.

2. The pH of the feces, and hence normal drainage, can quickly be controlled by the administration of starch in excess of the pancreatic threshold.

The Elimination of Various Dyes from the Pavlov Pouch of Dogs

By

SAMUEL MORRISON, M.D.*

DAVID L. REEVES, M.D.†

and

RAYMOND E. GARDNER, Sc.D.‡

BALTIMORE, MARYLAND

THE elimination of dye stuffs by the gastric mucosa in various pathological conditions of the stomach and the study of this elimination experimentally in animals has received rather extensive recognition in recent years. However, valuable contributions such as those by Dawson and Ivy, Kobayashi and Henning are at such variance, that further studies on dye elimination were hardly possible without re-investigating at least those points of difference so strikingly obvious in the above reports. Furthermore any evaluation of dye elimination-studies makes it imperative that the differences already referred to either be verified or disproved.

Cellular and histo-chemical studies which may explain the mechanism of dye elimination as well as its possible clinical application depend upon end results with which all authors are in agreement. In the case of dye elimination there is definite disagreement. Hence, we have initiated the present experiments on dogs with Pavlov pouches using a large number of dyes, which were tested and studied after their injection in approximately 1% aqueous solution, intravenously, intramuscularly, and through other channels.

DYESTUFFS ELIMINATED BY THE STOMACH THROUGH PAVLOV POUCH FOLLOWING INTRAVENOUS INJECTION

1. NEUTRAL RED—*Azine—Weakly Basic*—(Indicator)—1%—40 c.cs.—toxic in that quantity. Does not stain the mms. (mucous membranes) of the stomach or tissues. Through in less than 5 minutes. Also comes through in 1 c.c. quantities used intravenously, and in 1% strength.

2. NEUTRAL VIOLET—*Azine—Weakly Basic*—1%—20 c.cs.—not toxic to the animal in the amount used. Amply through within 5 minutes. Mms. of the stomach stained pinkish-purple.

3. MAGDALA RED—*Azine—Basic*—1%—25 c.cs. Mms. stained slightly pink. Not toxic.

4. SAFRANIN O—*Azine—Basic*—1%—25 c.cs. slightly toxic in this amount. Mms. of the stomach stained pink. Comes through definitely, but not to a considerable extent. This is an etherized dog; stomach brought out and examined.

5. METHYLENE BLUE—*Thiazine—Basic*—1%—20 c.cs. Slightly toxic. Mms. of the stomach stained slightly blue. Comes through when 1 c.c. of a 1% solution is injected and not toxic.

6. METHYLENE BLUE (SPECIAL)—*Thiazine—Basic*—1%—25 c.cs. Mms. of the stomach not noticeably stained with this quantity. Tissues, tongue, etc., slightly stained. Not toxic. Comes through definitely although not as much as plain methylene blue.

7. METHYLENE BLUE MERCK—U.S.P.X.—*Thiazine—Basic*—1%—30 c.cs. Somewhat toxic. Mms. of stomach, and the tissues not noticeably stained with such an amount. Comes through better than methylene blue, special.

8. NEW METHYLENE BLUE N—*Thiazine—Basic*—1%—25 c.cs. Not toxic, mms. of the stomach not stained with this amount.

9. AZURE II—*Thiazine—Basic*—1%—40 c.cs. Mms. of stomach purple. Not toxic.

10. TOLUIDINE BLUE—*Thiazine—Basic*—1%—25 c.cs. Not toxic-stains the mms. of the stomach little if any.

11. THIONINE—*Thiazine—Strongly—Basic*—1%—40 c.cs. Mms. of the stomach stained bluish. Slightly toxic.

12. TETRAETHYL THIONINE—*Thiazine—Basic*—1%—40 c.cs. Mms. of the stomach stained slightly purple or bluish. (A sacrifice animal).

13. THIONINE BLUE—*Thiazine—Basic*—1%—25 c.cs. Not noticeably toxic. Mms. of stomach, and the tissues slightly stained.

14. BISMARCK BROWN—*Azo Group—Basic*—1%—40 c.cs. in a sacrificed animal. Amply through in 2 minutes. Mms. of the stomach stained brown.

15. CHRYSOIDIN—*Azo Group—Basic*—1%—20 c.cs. Through within 5 minutes. Mms. of pouch not noticeably stained.

16. ORANGE G—*Azo Group—Acid*—1%—40 c.cs. Mms. colored. Not toxic.

17. CONGO RED—*Azo Group—Acid*—(Indicator)—1%—40 c.cs. Pouch dog. Not toxic. Mms. of stomach

*Assistant Professor, Department of Medicine, Clinic of Gastro-enterology, University of Maryland.
†Formerly Assistant in Surgery and Hunterian Fellow in Surgery, Johns Hopkins University.

Submitted August 22, 1927.

stained red. Comes through definitely but not to a great extent.

18. TRYPAN RED—*Azo Group—Acid*—1%—20 c.cs. Through within 10 minutes, moderate amounts.

19. EOSIN—*Xanthene—Acid*—1%—40 c.cs. Mms. of the stomach colored pink. Slightly toxic in that amount.

20. MERCUROCHROME — *Xanthene — Acid* — Not toxic. 1%—20 c.cs. amply through in 2 minutes.

21. ERYTHROSINE—*Xanthene—Acid*—1%—25 c.cs. Mms. stained pink. Not toxic.

22. PHYLOXINE — *Xanthene — Acid* — 1%—25 c.cs. Mms. of stomach stained deeply pink. Not toxic.

23. ROSE BENGAL—*Xanthene—Acid*—1%—20 c.cs. Not toxic. Within 5 minutes through, although not to a considerable extent. Mms. of the stomach slightly pink.

24. IOZENE (Commercial germicide) — *Xanthene — Neutral?*—2%—solution of neutral sodium salt of monomercurotetra-iodo fluorescein. 10 c.cs. used. About 2¼ c.cs. per kilo. Not toxic and came through within 5 minutes. Mms. of the stomach and tissues slightly pink in color.

25. BASIC FUCHSIN—*Phenyl Methane—Basic*—1%—10 c.cs. Quite toxic. Stains mms. of the stomach deeply. Continued to be eliminated for 3 days. Seems to have temporarily caused impairment of secretory cells.

26. LITHIUM CARMINE—*Indigo Group—Acid*—1%—40 c.cs. Stains mms. a dark pink. Comes through slightly. Not toxic under ether.

27. ETHYL CAPRI BLUE NITRATE — *Oxazin — Basic*—1%—40 c.cs. (Cohen and Preisser). Mms. of the stomach stained blue. Not toxic.

28. MALLOPHENE (W. C. Holmes) (Gall Bladder Dye) (Mallinckrodt)—1%—20 c.cs. Through in less than 5 minutes. Mms. of the stomach not stained. Not toxic.

DYESTUFFS ELIMINATED BY THE STOMACH THROUGH THE PAVLOV POUCH FOLLOWING INTRAMUSCULAR INJECTION

1. NEUTRAL RED — *Azine — Basic* — 1% — 25 c.cs. Flank intramuscularly. Through amply within 5 minutes. Mms. of the pouch not stained. Slightly toxic.

2. NEUTRAL VIOLET—*Azine—Basic*—1%—20 c.cs. Through amply within 5 minutes.

3. METHYLENE BLUE—*Thiazine—Basic*—1%—25 c.cs. Intramuscularly in the flank. Through in small amounts after 30 minutes.

4. METHYLENE BLUE MERCK—U.S.P.X.—*Thiazine—Basic*—1%—20 c.cs. Through definitely in ample amounts within 5 minutes.

5. AZURE II—*Thiazine—Basic*—1%—20 c.cs. Small amounts through within 20 minutes.

6. TOLUIDINE BLUE — *Thiazine — Basic*—1%—30 c.cs. Intramuscularly in flank. Appeared within 15 minutes, definitely, but in small amounts.

7. NEW METHYLENE BLUE N—*Thiazine—Basic*—2%—25 c.cs. Intramuscularly. Mms. not stained with this amount. Definitely through within 30 minutes. Not toxic.

8. BISMARCK BROWN—*Azo Group—Basic*—1%—30 c.cs. Not toxic. Came through slightly after 5 minutes. Mms. of the stomach pouch not stained with such an amount.

9. CHRYSOIDIN—*Azo Group—Basic*—1%—20 c.cs. Definitely through within 20 minutes.

10. CONGO RED—*Azo Group—Acid*—1%—20 c.cs. Definitely through within 5 minutes.

11. EOSIN — *Xanthene — Acid*—1%—40 c.cs. Intramuscularly in a sacrificed animal. Through slightly after 15 minutes.

12. PHLOXINE — *Xanthene — Acid* — 1% — 40 c.cs. Flank intramuscularly into pouch dog. Through in small amounts after 25 minutes.

DYESTUFFS NOT ELIMINATED BY THE STOMACH THROUGH THE PAVLOV POUCH FOLLOWING INTRAMUSCULAR INJECTION

All of the dyestuffs that had been eliminated by the intravenous route were tried intramuscularly with the exception of Basic Fuchsin, which was too toxic, and Ethyl Capri Blue Nitrate and Mallophene, which could not be obtained.

1. MAGDALA RED—*Azine—Basic*—1%—20 c.cs. Not through.

2. SAFRANIN O—*Azine—Basic*—1%—20 c.cs. Not through.

3. THIONINE BLUE—*Thiazine—Basic*—2%—25 c.cs. Flank intramuscularly. Mms. of the stomach not stained with such an amount. Not through. Not toxic.

4. SPECIAL METHYLENE BLUE—*Thiazine—Basic*—1%—40 c.cs. Not through after 20 minutes.

5. THIONINE—*Thiazine—Basic*—1%—20 c.cs. Not through.

6. TETRAETHYL THIONINE—*Thiazine—Basic*—25 c.cs. of a 1% solution. Not through after 30 minutes.

7. ORANGE G—*Azo Group—Acid*—1%—40 c.cs. Into flank. Not through after 30 minutes.

8. TRYPAN RED—*Azo Group—Acid*—1%—20 c.cs. Not through.

9. MERCHROCHROME — *Xanthene — Acid*—1%—20 c.cs. Not through.

10. ERYTHROSINE—*Xanthene—Acid*—1%—40 c.cs. Intramuscularly into flanks. Not through. Not toxic. Mms. not stained.

11. ROSE BENGAL—*Xanthene—Acid*—1%—20 c.cs. Not through.

12. IOZENE—*Xanthene—Neutral?*—2%—5 c.cs. Not through.

13. LITHIUM CARMINE — *Indigo Group*—1%—20 c.cs. Not through.

DYESTUFFS NOT ELIMINATED BY THE STOMACH THROUGH THE PAVLOV POUCH FOLLOWING INTRAVENOUS INJECTION

1. TRYPAN BLUE—*Azo Group—Acid*—1%—25 c.cs.

2. JANUS GREEN—*Azo Group—Basic*—1%—25 c.cs. Toxic. Not through. Repeated on an etherized animal with similar results.

3. DIAZINE BLACK (Janus Black)—C.I. 134—*Azo Group—Basic*—1%—25 c.cs. Quite toxic. Mms. of the stomach pouch not noticeably stained. Repeated twice on sacrificed animals, 1%—40 c.cs. Did not come through.

4. METHYL RED—*Azo Group—Weakly Acid*—1%—20 c.cs. Not toxic, and mms. of the stomach and tissues not stained.

5. BORDEAUX RED — *Azo Group — Acid*—1%—20 c.cs. Not toxic.

6. METHYLENE VIOLET—*Thiazine—Feebly—Basic*—1%—25 c.cs.

7. GALLOCYANIN — *Oxazin — Basic* — 1%—20 c.cs. Not toxic.

8. BRILLIANT CRESYL BLUE—*Oxazin—Basic*—1%—25 c.cs. Stained mms. pouch slightly. (?)

9. CRESYLECHTVIOLET — *Oxazin—Basic*—1%—25 c.cs. Not toxic and mms. of stomach pouch not stained with this amount.

10. NIGROSIN—*Indulin*—No. 128. W. C. Holmes—(not a pure dye)—*Acid?*—1%—20 c.cs. Slightly toxic.

11. INDIGO CARMINE—Indigo Group of Natural Dyes—*Acid*—1%—25 c.cs.

12. HEMATOXYLIN—Indigo Group of Natural Dyes

Foot Notes:

1. It is apparent that many of the dyes which come through after intravenous injection do not do so after intramuscular injection.
2. Many of the dyes are indicators and therefore have both acid and alkaline ranges. This is important in all of these studies.
3. The factor of absorption of dyes by muscles must be taken into consideration.

—?—20 c.cs. of 1% solution. Not toxic. Mms. of stomach pouch not stained.

13. VICTORIA BLUE — *Diphenylnaphthylmethane—Basic*—1%—25 c.cs. mms. of pouch not stained. Not toxic.

14. GENTIAN VIOLET—*Triphenyl Methane—Basic*—1%—25 c.cs. Tissues not stained and not toxic.

15. ETHYLVIOLET—*Triphenyl Methane—Basic*—1%—25 c.cs. mms. not colored. Not toxic.

16. METHYL BLUE—*Triphenyl Methane—Acid*—1%—25 c.cs.

17. LIGHT GREEN—*Triphenyl Methane—Acid*—2%—25 c.cs. *Not toxic and does not come through. Stains* tongue but not much of stomach.

18. ANILINE BLUE—*Triphenyl Methane—Acid*—1%—25 c.cs. mms. of pouch not stained.

19. PYRROL BLUE—*Triphenyl Methane—Acid*—1%—25 c.cs.

20. BRILLIANT GREEN—*Triphenyl Methane—Basic*—1%—25 c.cs. Not toxic, and mms. of the pouch not stained.

21. AURAMINE—(W. C. Holmes) C.I. No. 655—*Diphenyl Methane—Basic*—1%—20 c.cs. Not toxic, and mms. of the stomach pouch and tissues not stained.

22. AURAMINE G—(W. C. Holmes) C.I. No. 656—*Diphenyl Methane—Basic*—1%—20 c.cs. Not toxic. Doesn't stain mms. of pouch or the tissues.

23. PYRONIN—*Xanthene—Basic*—1%—10 c.cs. Toxic, not through. Repeated using 40 c.cs. of 1% solution. Mms. of stomach and the tissues stained slightly on a sacrificed animal. Doesn't come through.

24. ERYTHROSINE (Al. Salt)—*Xanthene—Acid?*—1%—20 c.cs. Not toxic. Mms. not stained. Repeated, 1%—40 c.cs. Not through. Doesn't go into solution readily.

25. PHENOLSULPHONEPHTHALEIN—*Xanthene—Acid—(Indicator)*—1%—25 c.cs.

26. THYMOL BLUE — *Xanthene—Acid—(Indicator)*—1%—20 c.cs. into a pouch dog. *Mms. not colored. Dye* is toxic.

27. BROM CRESOL PURPLE—(Dibromcresolsulphonephthalein) — *Xanthene—Acid* — (Indicator)—1%—20 c.cs. Not toxic and mms. of the stomach pouch not stained.

28. BROM THYMOL BLUE—(Dibromthymolsulphonephthalein) — *Xanthene—Acid* — (Indicator)—1%—20 c.cs. Not toxic, and mms. of the stomach pouch not stained.

29. CRESOL RED — (O-Cresolsulphonephthalein) — *Xanthene—Acid*—(Indicator)—1%—20 c.cs. Did not stain mms. of the stomach pouch. Not toxic.

30. CHLOR PHENOL-RED — (Dichlorphenol)—*Xanthene—Acid*—(Indicator)—Did not stain mms. of the stomach pouch or the tissues. Not toxic.

31. FLUORESCEIN — *Xanthene—Acid*—1%—40 c.cs. on a sacrificed animal. Mms. of the stomach not stained with this dosage. It did not come through.

32. ISAMINE BLUE—*Oxazine—Basic*—1%—25 c.cs.

33. BERLIN BLUE—*La*—Unclassified—1%—25 c.cs. Tissues not stained.

34. PONTAMINE SKY BLUE—(513)—5 BX—Unclassified—1%—25 c.cs.

35. PONTAMINE SKY BLUE—AX—Unclassified—1%—25 c.cs.

36. PHENOLINDOPHENOL — Unclassified—1%—25 c.cs. Mms. of pouch not colored.

37. TOLULENE BLUE — *Thinzine — Basic*—1%—25 c.cs.

38. PONTAMINE BLACK—EX—Unclassified—2%—25 c.cs.

39. BENZAMINE RHEIN BLAU — (513) — *Azo — Basic*—1%—25 c.cs. Not toxic. Mms. of stomach pouch not noticeably stained.

40. NATIONAL ALKALI BLUE—2GP. CI-710—Unclassified—1%—25 c.cs. Not toxic and mms. of the stomach not stained.

41. NATIONAL ALKALI BLUE—4GP—Unclassified—1%—25 c.cs. Not toxic and mms. of stomach pouch not stained.

42. PONTAMINE GREEN — Unclassified — 1% — 25 c.cs. *Not toxic. Mms. of the stomach pouch not stained.*

43. JANUS BLUE—Unclassified—1%—25 c.cs. Mms. of stomach pouch not colored. Slightly toxic. Repeated with confirmation on sacrificed animals, 1%—40 c.cs.

44. LEUCOFAST GREEN—FCF—Unclassified—1%—25 c.cs. *Not toxic, did not stain mms. of stomach pouch* nor the tissues.

45. INDIGO MONOSULPHATE—Unclassified—1%—30 c.cs. Not toxic. Mms. of stomach pouch not stained.

46. INDIGO TETRASULFONATE — Unclassified—1%—30 c.cs. Mms. of stomach pouch not stained. Not toxic.

47. INDIGO DISULFONATE—Unclassified—1%—30 c.cs. Mms. of stomach pouch not stained. Tissues slightly stained.

48. DIANIL YELLOW—R—C.I. 649—W.C.H.—Unclassified—1%—25 c.cs. Rather toxic. Did not stain mms. *of stomach pouch.*

49. RHODULIN VIOLET—Unclassified—1%—15 c.cs. Quite toxic. Mms. of pouch and mouth pink—skin pink.

50. ALIZARIN SAPHVIOLET—1187—Unclassified—1%—20 c.cs. Toxic. Mms. of the stomach pouch not stained. Not toxic.

51. PONCEAU de XYLIDINE—Unclassified—1%—20 c.cs. Not toxic. Mms. of the stomach pouch not stained.

52. TARTRAZINE—(NAC)—W.C.H.—Unclassified—1%—20 c.cs. Not toxic and not through. Mms. of stomach *pouch not stained.*

53. PONTACYL LIGHT YELLOW—GG—Unclassified—1%—20 c.cs. Mms. of stomach pouch not stained. Not toxic.

54. DIANIL YELLOW—3G—C.I. 647—Unclassified—1%—20 c.cs. Mms. of the stomach pouch not stained. Tissues not stained. Not toxic.

DYESTUFFS NOT ELIMINATED BY THE STOMACH THROUGH THE PAVLOV POUCH FOLLOWING ADMINISTRATION VIA STOMACH TUBE

1. Aqueous solutions, 1 gram per hundred of distilled water, in amounts of 20 c.cs. were administered by stomach tube to pouch dogs. All of the dyes were used which had been shown to be eliminated after intravenous administration, with the exception of three dyes: Iozene, Basic Fuchsin and Ethyl Capri Blue Nitrate. Iozene and Ethyl Capri Nitrate could not be obtained in further supply and the basic fuchsin was felt to be too toxic for consideration. None of the dyes were eliminated in the pouch after an hour following the administration.

2. Neutral red and Neutral Violet were then separately tried by stomach tube in alcoholic solutions. One gram of each per 100 c.cs. of 70% alcohol were used. 20 c.cs. being the amount administered in each case. These dyes only were used, because it was felt that they were eliminated as quickly by the stomach as any of those tried intravenously and intramuscularly. An hour following administration, neither had appeared in the pouch.

Foot Note:

1. "Tissues stained or not stained" refers to complete autopsies which offered the opportunity of examining tissues (organs) in general.
2. If the contents of the Pavlov pouches had been dropped into basic solutions various dye colors may have appeared indicating secretion in a leuco form. In other cases treatment with a weakly acidifying solution may likewise have produced color indicating reduction of dye in muscle or other tissues.

DYESTUFFS COMING THROUGH GASTRIC MUCOSA (POUCH) AFTER RECTAL INSTILLATIONS

1. These results have not been satisfactory or constant up to the present time. 100 c.cs. of 1% neutral red instilled into rectum had come through the pouch after 12 hours. In some instances it appeared faintly 40 minutes after injection. This work is to be repeated.

DYESTUFFS COMING THROUGH GASTRIC MUCOSA (POUCH) AFTER INTRAPERITONEAL INJECTIONS

1. Those dyes which came through after intravenous and intramuscular injections were tried. These results have not been satisfactory up to the present time. The rectal and intraperitoneal routes are mentioned now because the former has not been tried heretofore while the latter has had only limited trial.

Basic fuchsin appeared to be a toxic dye and after its use there was no secretion of HCl. The animals in which this occurred and two other animals which had developed marked hypochlorhydrias approaching achylias were utilized for the injection of dyes which were known to be eliminated through the gastric mucosa. These experiments are to be repeated. However, it is interesting that methylene blue 1%, 25 c.cs., was excreted only in the smallest amount (there was a small amount of HCl). Toluidine blue, 1%, 25 c.cs., was injected into the oldest collie dog in which little HCl was excreted and no dye appeared.

REMARKS

1. 1% solutions (1 gram per 100 c.cs. of water) were employed. The dyes did not always dissolve 100% in the solvent; a moderate amount of heating was necessary in some cases. In those instances in which a solution of 1 gram to 100 c.cs. could not be approximated or in which solution was brought about with difficulty the dye was omitted or if used attention is called to the solubility difficulties.

2. In the future the authors recommend that instead of saying the mucousmembrane of the stomach pouch was or was not stained, a thing difficult to be certain of, it would be better to compare the heavy staining of the mucous membranes by such dyes as lithium carmine and phloxine with that of methylene blue, which stained them very little; such could be designated as (4 plus), vs. (plus—). To establish a standard intensity of staining requires further work and for that reason we are not prepared to offer this simplified scheme at present.

3. "Unclassified dyes" refers to those dyes for which reference works (Schultz, Conn) offer unsatisfactory information regarding their groups and acidity or basicity.

4. Disagreement with Kobayashi:—(our work is in disagreement with many previous investigators but since Kobayashi has made the more recent and extensive studies we call attention to these differences so that the importance of the present study is understood).

1. He reports Janus Black being eliminated by intravenous injection. This did not occur with us, even though it was 3 times repeated, using as high as 40 c.cs. of a 1 gram per 100 c.cs.
2. Several dyes, acid, which he reports as not being eliminated following intravenous injection were found by us to be eliminated quite definitely, namely the following:
   1. Congo Red
   2. Eosin
   3. Erythrosine
   4. Lithium Carmine
   5. Phloxine
   6. Trypan Red (and among the basic dyes)
   7. Fuchsin

5. Basic dyes do seem to be the ones most suited for elimination, particularly is this so in the intramuscular injections, these being predominantly the basic dyes, and the dyes most quickly and abundantly eliminated. Neutral Red, Neutral Violet and Methylene Blue are basic dyes. However, the degree of basicity is not proportional to elimination as is shown by Thionine (a strongly basic dye), neutral red and neutral violet (weakly basic) and the other basic dyes.

For the purpose of clarity the following table of Conn showing the grouping of dyes is appended.

Dyes of the Nitro, Azo and Oxyquinone Groups:

1. The Nitro Group
   - Picric Acid
   - Martius Yellow
   - Aurantia
2. The Azo Group
   - Orange G
   - Bordeaux Red
   - Janus Green B
   - Fast Yellow
   - Methyl Orange
   - Orange IV
   - Orange I
   - Narcein
   - Amaranth
   - Sudan III
   - Sudan IV
   - Biebrich Scarlet, Water Soluble
   - Bismarck Brown Y
   - Congo Red
   - Trypan Red
   - Benzopurpin 4B
   - Trypan Blue
   - Chrysoidin R
   - Chrysoidin Y
   - Others
3. Oxyquinone Group
   - Alizarin
   - Alizarin Red S
   - Purpurin

The Quinone-Imide Dyes

1. The Indamins
   - Toluylene Blue
2. The Thiazins
   - Thionin
   - Methylene Blue
   - Methylene Azur
   - Methylene Violet
   - Methylene Green
   - Toluidine Blue O
3. The Oxazins
   - Brilliant Cresyl Blue
   - Nile Blue Sulphate
   - Cresyl Violet
4. The Azins
   a. Amido-Azins or Eurhodins
      - Neutral Red
      - Neutral Violet

b. *Safranins*
Safranin O
Amethyst Violet
Magdala Red
c. The Indulins
Nigrosin, Water Soluble

The Phenyl Methane Dyes
1. Di-Phenyl Methane Derivatives
2. Tri-Phenyl Methane Derivatives
a. Di-Amino Tri-Phenyl Methanes
Malachite Green
Brilliant Green
Light Green SF, Yellowish
b. Tri-Amino Tri-Phenyl Methanes (Rosanilins)
Parafuchsin
Rosanilin
Basic Fuchsin
New Fuchsin
Acid Fuchsin
Hoffman Violet
Methyl Violet
Crystal Violet
Gentian Violet
Methyl Green
Iodine Green
Spirit Blue
Methyl Blue
Amilin Blue
Others

The Xanthene Dyes
1. The Pyronins
Pyronin G
Pyronin B
2. The Rhodamines
Rhodamine B
3. Fluorane Derivatives
Fluorescein (Uranin)
Eosin, Y (i.e. Yellowish)
Methyl eosin
Ethyl eosin
Eosin, Bluish
Erythrosin, Bluish
Phloxine
Rose Bengal
4. Phenolphthalein and the Sulphonphthaleins
Phenolsulphonphthalein (phenol red)
Brom Cresol Purple
Thymol Blue
Others

The Natural Dyes
The Indigo Group
Indigo (Blue)
Indigo Carmin
Litmus
Haematoxylin
Others

Classification of important biological dyes based upon chromophores (Conn). (They can be further grouped into acid and basic chromophores).
1. The nitro dyes
e.g. picric acid
2. The Azo Group
e.g. methyl orange, Bismark brown, orange G, Congo red, Sudan III and Sudan IV
3. The Oxyquinone Group
e.g. alizarin
4. The quinine-imide group, including
a. Indamins
b. Thiazins; e.g., thionin, toluidine blue, methylene blue
c. Oxazins; e.g., brilliant cresyl blue, Nile blue
d. Azins, including
(i) Amido-azins; e.g., neutral red
(ii) Safranins; e.g., safranin O, magdala red
(iii) Indulins; e.g., nigrosin
5. The phenyl-methane dyes, including
a. Diphenyl-methanes, e.g., auramin
b. Diamino tri-phenyl methanes; e.g., malachite green, brilliant green, light green
c. Triamino tri-phenyl methanes; e.g., basic fuchsin, acid fuchsin, methyl violet, gentian violet, methyl green, anilin blue
d. Hydroxy tri-phenyl methanes (Rosolic acids); e.g., aurin, corallin red
6. The *Xanthene dyes, including*
a. Pyronins; e.g., pyronin G and B
b. Rhodamines; e.g., Rhodamine B
c. Fluorane derivatives; e.g., eosins, erythrosin, rose bengal
d. Phenolphthalein and the Sulphonephthaleins

DISCUSSION

No attempt will be made at present to review the literature on the subject of dyes. It is voluminous and the reviews are many. Only a few of the more recent contributions will be discussed since they are necessary for the sequential development of the problem at hand.

After the work of Fuld and Finkelstein, Hirabayashi thought it of interest to observe the excretion of neutral red under various produced pathological conditions. In normal stomachs he observed, through gastric fistulas, the appearance of neutral red after the administration of an Ewald meal, calcium carbonate, histamine, pilocarpine and alcohol. He concluded that the speed with which neutral red appeared depended upon the intensity of secretion of the secretory glands. He now washed the stomach with ½% silver nitrate solution and found that after observations extending over 2 hours no dyestuffs appeared in the stomach though the HCl secretion was persistent. After 48 hours the stomach again secreted normally following histamin and dye injection. From these and similar experiments it appeared to Hirabayashi that a local damage to the gastric mucosa diminishes the intensity of secretion and leads to a reduction in dye excretion over that shown for the normal stomach. The stimulation with silver serves also to show that the glands were not able to excrete dye but that the secretion of HCl was not interrupted. It is therefore possible, Hirabayashi concludes, that the dye is excreted through the pepsin glands. We repeated this experiment and are in disagreement as shown by the following data.

ELIMINATION OF DYESTUFF FOLLOWING INTRAVENOUS INJECTION AFTER THE STOMACH HAD BEEN TREATED WITH SILVER NITRATE SOLUTION

Ninety c.cs. of ½% solution of silver nitrate was administered to a pouch dog by stomach tube, and the pouch was washed with ½% silver nitrate solution. Ten minutes later 20 c.cs. of a 1% solution, aqueous, of neutral red was injected intravenously. Within 2 minutes the dye appeared from the pouch and in the stomach as amply as had been found previously. The same results were obtained with the stomachs of white rats.

Our results are entirely different from those of Hirabayashi, and they corroborate other conclusions

which we have been able to reach regarding the mechanism of neutral red excretion. This mechanism is of fundamental importance in the study of certain diseases as we hope to point out in future communications.

Dawson and Ivy studied the elimination of dyes by the gastric mucosa. They used dogs with an isolated fundic pouch (Pavlov Pouch) and dogs with an isolated pyloric pouch, the latter animals being used to ascertain if certain dyes were eliminated by the mucus cells. Of thirty-three dyes studied, thirteen were eliminated in the gastric juice. However, we were unable to corroborate these results in their entirety. Dawson and Ivy report a relationship between the amount of dye eliminated and the rate of secretion, i.e., the more gastric juice, the more dye eliminated. On the other hand, they report the elimination of neutral red through the pyloric pouch when the mucosa of the pouch was activated with gastric juice. It seems hardly possible that this was actual elimination, because we have been able to demonstrate a selective secretory mechanism for neutral red. Dawson and Ivy could not predict the effect of a dye from a study of its chemical constitution but they mention selective secretion as an obvious factor that must be considered in dye elimination, that is, some dyes may possibly be eliminated through the parietal cells, others, through the chief cells or mucus cells. Several dyes, of which neutral red is the best example they write, can be detected by microscopic examination to be passing out through the parietal cells as the secretion in the canaliculi is rendered conspicous by the dye. It would be difficult to correlate this finding with the elimination of neutral red through the pyloric pouch since the pylorus (unless the pouch included some oxyntic cells) contains no parietal cells. Dawson and Ivy believe that under certain conditions neutral red though most readily eliminated by the parietal cells, can be eliminated by the mucous cells of the stomach. They conclude finally that the parietal cells are the cells chiefly concerned in the elimination of dyes by the gastric mucosa and whether or not a dye is eliminated by these cells depends on some unknown as yet physical rather than chemical property of the dye as there is no chemical property characteristic of the dyes that are eliminated. Furthermore it seemed to them that the problem of dye elimination by the gastric glands has a greater scientific import than practical value. By comparing our Table with their's the importance of repeating these dye elimination tests becomes apparent. For example in our tests neutral violet came through amply, in the tests of Dawson and Ivy the result was negative. Moreover, the extensive reports of Kobayashi are not entirely corroborated by our investigations and attention has been directed to some of the differences.

Kobayashi has studied the absorption, secretion and excretion of dyes perhaps more extensively than any other recent investigator. He cannot agree with the conclusion of other investigators that the mechanism of the elimination of dyestuffs into the stomach could be explained simply by diffusion or that it depended on the gastric secretory function. He also disagrees with Hirabayashi's conclusions for he believes it must be the gastric glands and especially the parietal cells that secrete the dyestuffs. Matsuo as well as Glaessner and Wittgenstein, the latter in histological studies of neutral red elimination, support Kobayashi in this latter opinion. Kobayashi's experiments were very well controlled and minutely observed and he was able to correlate the concentration of eliminated dyes, hydrochloric acid and the pepsin. His experiments also confirmed the lack of relationship between the diffusibility of dyestuffs and their intensity of elimination; the lipoid solubility of dyestuffs did not explain their elimination into the stomach. Acid dyestuffs in general, were found not to be eliminated into the stomach even when soluble in lipoids. Our work would not support this observation although we too, found that basic dyes were predominant among those passing through the gastric mucosa. Kobayashi investigated 65 acid dyes; all of them had different properties physico-chemically or biologically, that is, in chemical construction, in diffusibility, in solubility in lipoids, or in vital staining, but none of them were perceived in the gastric juice.

Kobayashi concludes that the dyestuffs which are eliminated into the stomach are chlorides of dye bases and have amidogroups or their alkylsubstitutes in their auxochrome. They belong to the azo, azine, oxazine, thiazine or acridine group and their chromogens have all —N= in their chromophores and greatly resemble the fundamental unit of protein. They have some diffusibility and all have a positive charge. Kobayashi points out the resemblance in construction between these chromogens and the fundamental unit of protein and consequently he continues, "the dye bases of these dyes may be considered to have a construction similar to protein itself in some points." He suggests that this may be the reason why only the dyes of these groups can be eliminated into the stomach. Finally the elimination of dyestuffs is explained by a mechanism similar to the secretion of hydrochloric acid; he shows that his explanation harmonizes very well with the fact that when the parietal cells secrets HCl in a high concentration, they secrete dyestuffs in a relatively large quantity. The concentration of pepsin did not run parallel to that of the dyestuffs as exactly as the acidity. When the concentration of hydrochloric acid in the gastric juice is increased by a pilocarpine injection, the concentration of dyestuffs eliminated into the stomach is also increased and when the former is decreased by atropin. the latter is also decreased. Also with patients, Kobayashi found the curve of concentration of neutral red eliminated into the stomach after its administration into the blood circulation generally to run parallel with that of hydrochloric acid in the gastric juice. The work is indeed convincing and we have been able to corroborate it except that in our dye tests several acid dyes were found to be eliminated through the gastric mucosa. This finding necessitates another explanation of the mechanism of dye elimination than that offered by Kobayashi. The important fact however is the verification of the physiological mechanism of dye elimination. Knowing this, it becomes applicable for clinical use especially as a diagnostic measure to say nothing of the interpretation of pathological change which it allows. Further development of this topic will come later.

In 1932, Henning reported his work on the excretion of dyestuffs through the gastric mucosa of frogs. This work was based on some earlier clinical work which Henning, Jurgens and Orstein did in collaboration in 1931. The experimental arrangement was unique in that frogs, the gastric mucosae of which are almost

completely transparent were used while under the quieting influence of urethan. The stomach of the narcotized frog (urethan) was opened at the greater curvature and by an appropriate technique the excretion of a given dyestuff from the stomach could be followed visually in all its phases. The results obtained are remarkable when compared with Dawson and Ivy's and Kobayashi's for after testing a long series of dyestuffs it was shown that only acid dyestuffs are excreted into the stomach, provided they are in sufficiently fine dispersion; basic dyestuffs are not so excreted. As an example, the microscopical study of neutral-red excretion shows that the indicator in red color first appears on the surface of the mucosa, while it passes through the mucosa as neutral yellow. Accordingly, the gastric hydrochloric acid is first formed on the covering epithelium. The dyestuff excretion Henning reports "is a function of the fundus glands: the antrum glands do not participate." Dawson and Ivy reported neutral-red excretion through a pyloric pouch in the dog. The excretory function of the gastric mucosa, Henning concludes, is connected with the secretory function. It can be elicited in secretory rest by means of secretory stimulants (histamin). In other words, the excretory function of the gastric mucosa is closely related to the secretory function; it stops on secretory rest and can be elicited through histamin. Uranin (fluorescein), eosin, erythrosin (all acid xanthene dyes) neutral red (weakly basic azin), Congo red (acid azo) magdala red (basic azin), trypan blue (acid azo) and methylene blue (basic thiazin) were a few of the dyes which came through the gastric mucosa. It will at once be seen that 3 of these dyes are basic which makes it difficult to understand the conclusion that only acid dyes are eliminated, except that Henning refers to neutral red as an indicator dye and therefore acid as well as basic. Furthermore, except for Henning there is general agreement that trypan blue is not eliminated through the gastric mucosa. We found that it was taken up by the phagocytic cells but was *not* in the glandular cells. Moreover, in our work trypan blue was injected intravenously into a rabbit and followed by neutral red; the latter appeared through the gastric mucosa but the trypan blue did not. Henning finds that trypaflavin is taken up by entirely different cells than uranin. The dyes mentioned above all electively begin to stain the capillary walls, the submucous connective tissue and the glandular cells. Henning recalls the extensive experimentation on albino rabbits of F. P. Fisher who showed that the different behavior of the dyestuffs is determined by their colloid constitution and that the fate of dyestuffs which have been introduced into the blood current, is governed by the degree of dispersion, the electric charge and surface tension phenomena.

SUMMARY

In order to furnish a working basis for further investigations it has become essential to repeat the study of dye elimination through the gastric mucosa. Without reviewing the voluminous literature, three representative and rather recent papers are examined to show how extremely varied the results have been. Often the differences are so extreme that reasons are sought to explain them either in the type of experimental animal, the method of experimentation or the interpretation of results. It becomes apparent that our interpretations explain some of the incongruities but there still remains a fundamental difference in results. All are agreed that it is the fundus mucosa which eliminates those dyes which are excreted. We too, have reached this conclusion but furthermore, we have found that both acid and basic dyes are eliminated (more of the latter) which differs from the results obtained by the other investigators. Many dyes may be both acid and basic. In fact, the acid or basic reaction of many dyes depends on the nature of the subgroups which confer water solubility upon the molecule. Our work corroborates parts of each of the other investigators but not enough to substantiate any of their explanations of the mechanism of dye elimination nor the reasons for selective elimination. It would seem that size of dye particles apparently plays little role since it has been shown by the ultrafiltration experiments of Allisbaugh and Hyde that methylene blue, a dye readily eliminated, is considerally larger in particulate size than a dye definitely withheld. Careful study of the present investigation leads us to the conclusion that it represents a reliable basis for the studies which we are pursuing but it does not allow us, as yet, to explain either mechanically, physiologically or chemically dye elimination by the mucosa. This we hope to do in a future communication.

SECTION III—*Nutrition*

On the Probable Frequency of Allergic Shock

By

WARREN T. VAUGHAN, M.D.
RICHMOND, VIRGINIA

and

DAVID M. PIPES, M.D.
SHREVEPORT, LOUISIANA

A REVIEW of the literature reveals surprisingly few accounts of clinical anaphylactic shock. In spite of what we consider the relative frequency of these events they have received comparatively little attention in recorded reports.

Lamson in a meticulous review of the literature from 1895 to 1923 reported "41 cases in which death may have been due, directly or indirectly, to protein injections." These fatalities, in tabulation, are as follows: from diphtheria antitoxin, 31; anti-tuberculosis serum, 1; normal horse serum, 2; anti-streptococcus serum, 1; tetanus antitoxin, 2; antipneumococcus serum, 1; proprietary biologic product for muscular rheumatism, 1; liquid glue, 1; and probably ovomucoid, 1. In this series he included five personal observations; four from diphtheria antitoxin and the fifth due probably to ovomucoid. In the same series Lamson reported 21 additional cases "in which information was lacking, or in which death seemed due to primary disease or some other cause not associated with injected substances." These included: from diphtheria antitoxin, 13; anti-meningococcus serum, 4; anti-staphylococcus serum, 1; pneumococcus antibody solution, 2, and human blood transfusion, 1. Since Lamson's report there have appeared several references to shock from serum and other proteins, and non-nitrogenous factors as well, but their sparseness is noteworthy in view of the fact that administration of protein and non-protein agents for diagnosis, prophylaxis and treatment has been on the increase.

We have reviewed the literature from the period of Lamson's report up to and including 1935 as recorded in Table I. These cases include reactions not only to serum and other proteins, but to non-nitrogenous substances as well. They are classified as to number of cases, method of administration of shocking agents, and outcome. Of the 68 cases those associated with serum administration are in the majority, numbering 35. These include hemoplastic preparations, anti-meningococcus serum, diphtheria antitoxin, anti-streptococcus, plain horse and anti-pneumococcus sera. Other causes of shock were bee sting (4 cases); aspirin (3 cases); wasp sting (2); egg white (2); milk (2); rye (1); grass pollen extract (1); glue (1); sodium iodid (1); bismuth tartrate (1); rabbit hair inhaled (1); green pea (1); quinine hydrochloride (1); walnut (1); buckwheat (1); feather extract (1); commercial cold vaccine (1); ovomucoid (1); blood transfusion (2); puncture of hydatid cyst (4); and gum acacia (1).

The methods of administration or exposure were varied. The *intramuscular* route included ten serums and one milk; *intravenous*, two serums, 1 milk, 1 sodium iodid, 1 bismuth tartrate; *oral*, 1 milk, 1 green peas, 3 aspirin; *inhalation*, 1 rabbit hair; *intracutaneous*, 1 serum, 1 glue, 2 egg white, 1 buckwheat, 1 ovomucoid; *subcutaneous*, 12 serum, 1 morphine, 1 Bermuda grass pollen, 1 commercial cold vaccine; *scratch*, 1 walnut, 1 rye; *transfusion*, 2, and *"unknown,"* 20.

The "outcomes" are classified as fatal, recovered and unknown.

Not all of the cases included can properly be described as clean cut. Severe reactions have been observed following blood transfusions, even though apparently satisfactory matching had been accomplished beforehand. Bender and Traum have described anaphylaxis following blood transfusion which they attribute to serum idiosyncrasy. Waldbott in describing a case which reacted to feather extract, states that the reaction was not typical or similar to that following injection of pollen extract. The feather extract, which he believes to have been given intravenously by accident, gave rise to a severe migrainous headache with vomiting and cloudy spots before the right eye, manifestations which the patient had frequently experienced before. The same type of reaction occurred in his case who was given therapeutic extract for eczema, resulting in a severe generalized urticaria.

It is interesting to note that Lamson found in his survey (up to 1924) only two reported cases of anaphylaxis from substances other than serum. In 1922, Cooke described a case of shock occurring from liquid glue applied as a diagnostic skin test. The other case was a personal observation by Lamson of shock from diagnostic skin test which he thought to be due to ovomucoid. In the surveys represented herein there are only 35 cases of serum shock, representing 52 per

Submitted June 8, 1936.

cent of the entire series. Of the remaining cases 27 or 38 per cent of the total were shocked from protein other than serum, while 7 or 10 per cent of the total were shocked from non-protein substances.

Although the literature as briefly reviewed above would indicate that severe allergic shock and death are extremely infrequent, we have felt that in view of the widespread use of allergenic materials the possibility existed that the phenomenon was much more frequent than appeared. This would be especially likely to be the case in view of the natural disinclination that many would have towards reporting unfortunate experiences.

When therefore, in 1935, one of us was demonstrating an exhibit on allergic shock at the meeting of The American Medical Association, an effort was made to interview as many as possible of the doctors who stopped at the booth, concerning any experiences that they had had or had known of among their colleagues. While this was purely a random selection the possibility must be acknowledged that a physician who had had an unfortunate experience of this type would be more likely to stop at the booth.

A total of 50 physicians was interviewed, 25 of whom had either personally observed severe shock or knew of such cases among colleagues in their home towns. For obvious reasons names and addresses were not asked but as much information as could be was obtained from the informants.

Two types of case were excluded: those that had been reported in the literature, and those of what we term "severe allergic reaction." A severe case of urticaria or even asthma following the administration of an overdose of pollen extract is a severe allergic reaction but is not shock. We feel that allergic shock is a much more explosive affair, developing with extreme rapidity, once it has started, and due in all probability to a quite generalized tissue edema, including interstitial edema of the lungs, and due to almost universal increase in capillary permeability. The mechanism is probably quite similar to that responsible for urticaria and differs principally in its extremely widespread distribution. It should be borne in mind that the capillaries of the muscles alone in the average man have a total area of approximately 6,300 square meters, or more than 3,000 times the area of the entire body surface. It has been stated that in the absence of restraining forces, the entire plasma volume could pass from the capillaries into the body tissues within ten seconds. (Editorial: "Capillary Pressure and Capillary Permeability." *J. A. M. A.*, 103:920, 1934). With this in mind persons were asked particularly regarding the presence or absence of urticaria and asthma. While some of those interviewed were uncertain the number who stated definitely that the symptoms were not inaugurated with urticaria or asthma was surprisingly large. This will be brought out below.

Some reactions, notably those to drugs are probably not allergic but are included for general interest and because they were mentioned.

In an effort to provide some sort of a check on these random interrogations and to see whether sampling of a slightly different type of population would give materially different frequencies, one of us repeated the procedure in the autumn of 1935 at the meeting of The Medical Society of Virginia. Twenty-five physicians were interrogated, of whom 14 described cases of shock.

The information obtained is briefly summarized in the accompanying table.

Some of the more interesting cases were described as follows:

SERUMS AND ANTITOXINS

There was one death from plain horse serum given subcutaneously for postpartum hemorrhage.

A boy had had tetanus antitoxin two years previously. On the second injection of antitoxin he developed typical anaphylactic shock.

A person was given tetanus antitoxin prophylactically into the abdominal muscles. One minute later he developed angioneurotic edema of the face and wheezing. He could not breathe. He was given adrenalin with relief. Six days later he had regular serum sickness. Three years previously he had had toxin-antitoxin. During childhood he had facial eczema.

The reaction in another case followed intracutaneous testing with 0.1 c.c. of tetanus antitoxin diluted 10 times. The reaction commenced before the dector could get the syringe cleaned. It consisted of nausea, vomiting, sneezing, asthma and urticaria. Treatment with adrenalin resulted in prompt relief within half an hour.

A cook had diphtheria. There were twin daughters in the home. One of them had been subject to hives. The father, a physician, gave the second daughter, not subject to hives, 1000 units of diphtheria antitoxin prophylactically. She was dead in five minutes.

A child had diphtheria and the physician decided to immunize the entire family. The father dropped dead.

A colored boy with diphtheria received antitoxin. There had been no previous serum administration. He went into collapse within three minutes. There was no urticaria. He received adrenalin with subsequent recovery. Four days later he had serum sickness.

A patient with scarlet fever was given erysipelas streptococcus antitoxin. The intracutaneous test had been negative. He received 2 c.c. intravenously over a period of ten minutes. "One hour later" he had a severe reaction with cyanosis, respiration 45, pulse thready, blood pressure 120, going later to 70. Relief was obtained after about 45 minutes with adrenalin. There was no allergic history and no previous serum injection.

Scarlet fever antitoxin was given to a patient who had previously received serum of some kind. Within five minutes he was in collapse and pulseless. He was given adrenalin and recovered from the acute response but died later from the scarlet fever.

A patient with pneumonia was given anti-pneumococcus serum which was very promptly followed by coma. The pulse was very slow. The physician thinks that the condition may have been psychic.

POLLEN EXTRACTS

A physician had been giving himself his own shots of prophylactic ragweed pollen extract. He was toward the end of the series. He had a typical shock type of reaction without urticaria, hay fever or asthma. This began within five minutes after the injection. The physician stated that if he had waited five minutes longer he could not have left his chair to get the adrenalin. Prompt relief was obtained in ten or fifteen minutes following adrenalin injection. He has not taken any treatment since. He had taken courses of treatment for the five previous years, but had never obtained extremely good results.

A traveling man had been in the habit of rushing into various doctors' offices, wherever he happened to be, getting the doctor to give him a shot of pollen extract and then promptly rushing back to his car and driving on. One day he followed this customary procedure in a small West Virginia town. After he was back on the road he

went into shock. He did at last manage to get to a farm house from where a physician was called.

A patient received his fifth injection of ragweed extract. He promptly went into coma and respiration ceased. He was pulseless. The patient eventually recovered. The doctor feels confident that this was not psychic.

A patient was being desensitized with ragweed extract. Injections were given every third day. Within one minute after the fourteenth treatment the patient collapsed, with loss of sphincter control and coma. During recovery he commenced to have hives. During shock the pulse and respiration were slow. Treatment was given with adrenalin, with recovery in 30 to 60 minutes. The next day he was entirely himself again.

A patient had been receiving perennial ragweed treatment with two injections monthly. He missed one dose and at the end of thirty days came in for treatment. He was given the usual 0.1 c.c. of 1 33 concentration. He walked to his office five minutes away and then promptly went into coma. He had enough intelligence to take an ephedrin capsule before losing consciousness and his assistant applied a tourniquet. One hour later he was entirely all right. No adrenalin was administered.

A patient had been receiving injections of ragweed oil for ragweed dermatitis. He went into shock within two minutes which was followed by severe abdominal pain and extreme headache whenever he would raise his head, all of which lasted about five hours. He did not lose consciousness. There was little urticaria and no asthma. Following this his ragweed dermatitis was entirely cured for several weeks.

A patient was being desensitized with timothy extract, had left the doctor's office and was working beneath his automobile. He had typical anaphylactic shock and had great difficulty in getting out from under the car to procure aid. This was an early small dose of timothy extract.

A woman, aged 60, had received preseasonal and coseasonal pollen treatment for six or seven years without benefit. After an interval of several years without treatment she saw a new doctor who gave her preseasonal and coseasonal treatment with very satisfactory results. A year later, at the onset of symptoms, she received 0.1 c.c. of 1 10,000 mixed ragweed. This was from the same bottle that had been used the previous year. Within thirty seconds she was comatose and in convulsions. The coma lasted about five minutes. This was followed by slight urticaria and pronounced asthma. She remained seriously ill for an hour and a half. Following this one episode she had no further treatment for the season and had no hay fever. One year later, during the season she had ten or eleven coseasonal injections with good results.

A case of anaphylactic shock occurred during desensitization therapy with extract of rose pollen. This was early in the treatment, the third injection.

ALLERGY TEST MATERIALS

A negro orderly in a hospital who received a scratch test with 3 per cent concentration of ragweed extract collapsed and went into coma within three minutes. Blood pressure was 85. Pulse was rapid and thready. Respiration was normal. He remained unconscious for half or three-quarters of an hour. He was treated with adrenalin. Late during the period of collapse, before complete recovery, he developed urticaria. There were no nasal or bronchial symptoms. During the preceeding three years he had had coseasonal treatment with perfect results, receiving only three or four injections each season.

The wife of a farmer inhaled large quantities of smoke when the barn burned down. Thereafter she would always have attacks of asthma when wood fires were lighted in the fire place. She was tested with extract of wood smoke. Extract of wood smoke is prepared commercially for the curing of ham. Following the scratch test she promptly went into collapse but recovered.

In another case scratch test with streptococcus vaccine had been negative. The same material was then tried intracutaneously. A systemic reaction followed within sixty seconds. This was accompanied by asthma and urticaria. It lasted for two hours and required a total of 3 c.c. of adrenalin for relief.

An intracutaneous test with 0.05 c.c. of concentrated horse serum, preliminary to the administration of antitoxin resulted in death within five minutes. There had been no previous scratch test.

An intracutaneous test with 1/10,000 dilution of annual sage extract promptly resulted in a very strong intracutaneous reaction with generalized itching, generalized urticaria, brassy cough, asthma, blood in the sputum and vomiting. Adrenalin had to be administered every 50 minutes throughout a period of twenty-four hours. The reaction was followed by an anuria, after which so much albumin appeared in the urine as to produce a solid clot in the test tube. The patient received a total of 60 injections of adrenalin. As the physician expressed it "all of her mucous membrane were involved including the kidneys."

FOODS

A doctor described two instances of collapse in infants when first given cow's milk. In each case the child vomited, became very pale and the family thought he was dead. One of these children had no hives, the other had hives during recovery only.

A case of anaphylactic shock was described following the eating of egg. This boy had been to a Thanksgiving dinner and ate some mashed potatoes to which egg had been added. The child went into coma, two or three doctors were called and three hours elapsed before recovery.

A man sensitive to ragweed promptly went into shock without asthma or urticaria following the eating of wild honey. The physician is of the opinion that it was due to the ragweed pollen in the honey. It is well known that bees deposit quantities of pollen in honey.

After the eating of a single cherry a woman promptly experienced angioneurotic edema of the mouth and edema of the larynx. She had had a similar experience from a blackberry pie at another time. Adrenalin gave relief on both occasions. This was early in the days of adrenalin therapy and the physician gave her 2 minims of 1/1000 intravenously. Thereupon he thought that she died. "She stiffened out, took a long breath, and was all right."

DRUGS

A man, aged 55, knew that even the touching of his lips with aspirin would result in cyanosis and asthma within thirty seconds. On an occasion he had a headache and a friend gave him a powder which, unknown to him, contained aspirin. This resulted in a severe reaction which lasted five hours and required several doses of adrenalin.

Powdered aspirin was applied to the throat following tonsillectomy, in a man of 35 years. It promptly produced intense dyspnoea and cyanosis. The patient cried out, "My God, what did they give me?" He had had similar experiences previously from aspirin. Adrenalin administration was followed by recovery.

A five grain aspirin tablet caused prompt shock, collapse and cyanosis. There was no urticaria. There was some subsequent pulmonary edema but no asthma. Adrenalin administration resulted in recovery in a few minutes. The patient had had aspirin before but never with severe symptoms.

An asthmatic patient with low blood calcium was receiving calcium gluconate intravenously. At about the time when he commenced experiencing heat in his mouth he broke out into a cold sweat and according to the doctor went into typical shock. Treatment was with adrenalin and recovery was slow.

A colored woman received an injection of neoarsphenamin. She had had several previously. To this one she

TABLE I

Method of Administration

Substance	Number of Cases	Intram.	Intrav.	Oral	Inhalation	Endermal	Subcut.	Scratch	Transf.	Unknown	Outcome Fatal	Outcome Recov.	Outcome Unknown
Serum	35	10	2			1	12			10	11	13	11
Morphine	1						1						1
Bee sting	4											4	
Milk	2	1		1							1	1	
Pollen Berumda grass	1						1				1

Ovomucoid	1					1					1		
Aspirin	3			3							3		
Hydatid cyst punctured	1												
Gum acacia	1		1									1	

reacted with vomiting and collapse. Adrenalin was given with recovery.

A death was reported five minutes after an intravenous injection of neoarsphenamin.

BIOLOGICALS

A woman was sensitive to veal, ragweed, June grass and orchard grass. For an attack of menorrhagia she was given Antitutrin S. At once she developed urticaria, became cyanosed and went into shock. The doctor expressed it that she puffed up like a pouter pigeon. There was coughing and vomiting. Treatment was administered with adrenalin and it required four or five hours before recovery. The urticaria persisted for four or five days. She had been tested with veal some time previously and had reacted positively thereto by skin test. She had avoided veal since childhood. This patient was subject to attacks of petit mal.

Brook's hemoprotein has been used as foreign protein therapy for sinusitis. In one case its administration was followed promptly by severe constriction of the bronchial muscles, itching of the mouth and scrotum. Reaction was almost immediate. Adrenalin was given, with prompt relief. There had been several similar injections previously without untoward effect.

Early in the course of intramuscular liver therapy a first intramuscular injection was given. The patient had previously taken liver extract by mouth. Within three minutes she was pulseless and syanotic. There was no urticaria, hives nor asthma. She was treated with adrenalin, with prompt recovery. Other cases had been given the same batch of liver extract intramuscularly without untoward results.

INSECT BITES

Two school girls, sisters, were stung by bees. In both cases there was prompt "spasm of the bronchial tree" during which they became intensely cyanosed and went into collapse. One had generalized urticaria and the other did not. Both were treated with adrenalin, with relief.

A man, bitten by a bee, collapsed in the yard before he could reach the house. He had generalized edema with edema of the glottis. This was fifteen or twenty years ago, before the advent of epinephrin. It required several hours for recovery.

A woman standing in the kitchen door was stung by a bee. She collapsed before she could reach the dining room. When reached she was in shock and pulseless. Treatment with adrenalin quickly relieved her. She had a similar experience a second time.

A man was bitten by eighteen or twenty bees, all of the stings being on the right arm. He died after forty-eight hours, following prolonged collapse. At autopsy there was generalized edema in the distribution of the right axillary artery and the right vertebral artery. He developed urticaria soon after he had been stung and this disappeared following epinephrin treatment, but the patient did not recover.

One death was reported from a wasp sting.

One case of shock described as "six plus" was reported from a bed bug bite.

TABLE II

Cases of severe anaphylactic shock or death

Substance Causing Reaction	Mode of Administration or Contact	Shock	Death
	Serums and Antitoxins		
Horse serum	Subcutaneously	3	1
Horse serum	Not known		1
Tetanus antitoxin	Intramuscular	1	
Tetanus antitoxin	Not known	1	
Tetanus antitoxin	Not known		1
Diphtheria antitoxin	Therapeutic	2	
Diphtheria antitoxin	Therapeutic		2
Diphtheria antitoxin	Prophylactic		2
Streptococcus antitoxin	Intravenous	1	
Scarlet fever antitoxin	Not known	1	
Antipneumococcus serum	Not known	1	
	Pollen Extracts		
Ragweed extract	Therapeutic	7	
Ragweed extract	Therapeutic		2
Timothy extract	Therapeutic	2	
Rose pollen extract	Therapeutic	1	
	Extracts for Allergic Testing		
Ragweed	Scratch test	1	
Wood smoke extract	Scratch test	1	
Orris root	Scratch test	1	
Streptococcus vaccine	Intracutaneous	1	
Pure lactalbumin	Intracutaneous	1	
House dust	Intracutaneous	1	
Horse serum (undiluted)	Intracutaneous		1
Annual rare pollen	Intracutaneous	1	
Mule dander	Intracutaneous	1	
Tetanus antitoxin	Intracutaneous	1	

TABLE II (Continued)

Cases of severe anaphylactic shock or death

Substance Causing Reaction	Mode of Administration or Contact	Shock	Death
	Foods by Mouth		
Milk	Ingestion	2	
Eggs	Ingestion	2	
Beer	Ingestion	1	
Wild honey	Ingestion	1	
One cherry	Ingestion	1	
Blackberry pie	Ingestion	1	
Honey	Ingestion	1	
Soy bean	Ingestion	1	
	Drugs		
Quinine	Orally	1	
Aspirin	Orally	3	
Novocain	Intraurethrally		1
Iodized oil	Intraurethrally	1	
Calcium gluconate	Intravenous	1	2
Neoarsphenamin	Intravenous	1	
	Biologicals		
Antuitrin "S"	Subcutaneous	1	
Colon bacillus vaccine	10,000 dose, intravenously	1	
"Brooks hemoprotein"	Subcutaneous	1	
Liver extract	Intramuscular	1	
Pecan extract	Therapeutic	1	
	Insect Bites		
Bee sting	Bite	4	
Bee sting	Bite		2
Wasp sting	Bite		1
Bed bug	Bite	1	
	Transfusion		
Egg in donor's diet	Intravenous	1	
Milk in donor's diet	Intravenous	1	
	Physical Allergy		
Sunlight	Prolonged exposure	1	

TRANSFUSION

The recipient was allergic to egg. The donor ate eggs about two hours before transfusion. After receiving 75 c.c. of blood the recipient experienced severe dyspnoea. He was placed in an oxygen tent and given adrenalin with recovery. Although he had previously had eczema he had never had asthma before. Direct blood matching and matching by groups had shown compatibility prior to the transfusion.

PHYSICAL ALLERGY

A woman extremely sensitive to sunlight was preparing to take a bath. Her telephone which was in an upstairs sun room rang and she proceeded to answer the phone, unclothed. She stood in the direct sunlight talking for some time and then went into collapse.

DISCUSSION

Certain of the cases mentioned are probably not instances of allergic shock. Such are the reaction of anti-pneumococcus serum, which may have been psychic; that to ragweed oil which may have been embolic; that to calcium gluconate which may have been vasomotor; the neoarsphenamin reactions; the reaction to intramuscular liver extract; and the fatal bee sting case which sounds more like a virus or venom death than anaphylactic.

In one or two cases there might be a difference of opinion as to whether we are dealing with severe allergic reaction or true anaphylactic shock.

Such cases are included, however, since they well represent the different types of shock reaction which a physician may at some time encounter following

therapeutic measures. It seems probable that a poll of physicians, sufficiently large to possess statistical value, would show a lower frequency, but the fact that 50 per cent of those interviewed had either seen or had first hand knowledge of severe reactions of this sort, would indicate that they are much more frequent than the literature on the subject would lead us to believe. Although parenteral medication has come into very widespread use and, considering its frequency, is rarely accompanied by untoward results, the risk should be realized and proper precautions should always be employed.

PRECAUTIONS

The precautions which will do much toward preventing untoward reactions are tabulated below as they appeared in the exhibit referred to above.

A B C OF PREVENTION

Allergy Consciousness. Before injecting a foreign substance enquire concerning:

Idiosyncrasy
  Foods, drugs, sera, horses, etc.
Allergic history
  Asthma, hay fever, urticaria, migraine abdominal allergy. (In order of importance)
Family history of outspoken allergy
Previous medications and reactions thereto (especially serums)

Beforehand. Make preliminary diagnostic tests for idiosyncrasy to biologicals:

Skin
  Scratch followed by intracutaneous
Conjunctiva
  Serums and pollens
Mucous membranes
  Drugs, foods, etc.
Subcutaneous
  If in doubt give extremely small dose subcutaneously, and await reaction

Care. Be sure proposed dose is correct
Use an extremity for preliminary injection
Apply tourniquet above injection if allergic reaction ensues
Administer epinephrin in opposite arm

TREATMENT

If shock has occurred. Symptoms:

Severe—within a few minutes
  Collapse
  Death
Moderate—after several minutes
  Sneezing barrages
  Urticaria
  Asthma
  Vomiting
  Diarrhea

First:

Apply tourniquet above site of injection
Inject epinephrin into opposite arm or above tourniquet —repeat if necessary
Provide complete rest
Apply cold to skin if there is urticaria

Later:

When relieved, release tourniquet temporarily
  Reapply on return of symptoms
Keep alternating, release and reapplication until symptoms no longer appear after release

Treatment of obstructive asphyxia. In bronchial asthma and asthmatic bronchitis:

Find and remove offending allergens
Bronchial relaxants
  Epinephrin
  Ephedrin
  Atropin derivatives
Expectorants
Oxygen
Bronchoscopy

In angioneurotic edema of air passages:

Epinephrin
Cold applications
Intubation
Tracheotomy

Diagnosis is important:

"Not all that wheezes in asthma"
Use available aids such as X-ray, bronchoscopy, etc., to be certain that the cause is not
  Foreign body
  Malignancy
  Aneurism
  Infection, etc.

Desensitization. When serum tests are positive, and yet the patient must have serum:

Dilute the serum, serially 10x: 100x: 1000x: 10,000x
Scratch skin with these serial dilutions
Start desensitization with that dilution which just fails to react positively
Give injections hypodermically every half hour
Have epinephrin and tourniquet at hand
Always give desensitizing doses in extremities
Double the strength of dose each time, going up through the several dilutions

If treatment must be given intravenously it is usually safe to start half hourly intravenous injections after one has passed the dose of 2 c.c. hypodermically.

Start the intravenous treatment with one-tenth c.c. or less. It is also well to drop back to a somewhat more dilute extract

Continue doubling the dose until the proper total dose has been administered

The above program holds in most cases

A few who appear to be congenitally hypersensitive to serum, appear not to tolerate even this method of desensitization.

The Clinical Significance of Indicanuria*

By

HORACE W. SOPER, M.D., F.A.C.P.
ST. LOUIS, MISSOURI

A REVIEW of the literature of indicanuria discloses that much confusion exists. The physiologic chemists do not agree in their conclusions and many clinicians decline to accept indicanuria as a clinical entity. The prevailing opinion among gastroenterologists appears to be that excess of protein in the diet and constipation are the chief etiologic factors. Underhill and Simpson (1) conclude "that phenol and indican excretion bear quite a different relation to one another. That constipation overshadows the effect of diet and causes a large increase in the excretion of both indican and phenol." Meat ingested in large quantities, caused a marked increase in both substances. Morgan (2) noted that indicanuria was greatly increased in typhoid, peritonitis, and cholera. In true autointoxication, indican rarely disappears.

Seyal (3) found no correlation between constipation and indican excretion. Verbrycke (4) considers indolic autointoxication a very real entity, and is independent of constipation. Diet will not alter the condition and acidophilus treatment is useless. Plansker (5) found large indican content in the first and second months of life. Constipation of the patient seems to be the great factor. It is increased in infections and diarrheas. The administration of sugar caused a decrease or disappearance of the indican. Moewes (6) found a large indican content in achylia gastrica patients. Baar (7) recommends high colonic lavage as treatment. Levin (8) excludes meat and eggs, and feeds a diet consisting of cereals, vegetables, fruit and milk. Because of lack of space, I omit many references.

My object in this paper is to present my own clinical experience. In the year 1917, I determined that each patient's urine should be examined for indican regardless of the nature of the illness.† The urine voided during the night from bedtime to breakfast was selected. Obermayer's test was employed, designating one, two, three and four plus reactions. The number of patients examined since that time is 18,006. For the purpose of this study only those cases showing a "four plus" reaction were utilized inasmuch as it is exceedingly rare to find a specimen of urine that does not show "one plus," and I wish to present only the strongly positive reactions. 15% (2700) of the total disclosed a 4 + indican reaction. Intensive study of this list of cases revealed that patients suffering from practically every disease were included in the 4 + reactions. However, it gradually became evident that certain diseases predominated, *e.g. achylia gastrica, duodenal ulcer*, and *"toxic" headache.*

The *achylia gastrica* cases numbered 530. All of these patients were subjected to fractional stomach content analyses. Of this number 98% revealed indican 4 +. Dietetic treatment and exhibition of full doses (4 c.c.) dilute HCl. corrected digestive symptoms and greatly improved the patients' general nutrition but had no effect in diminishing the indican content of the urine.

The *"toxic" headache* cases numbered 696. Headaches due to nasal sinus conditions, eye disorders, syphilis, arterio-sclerosis, allergy, hypertension, etc., were excluded from this list. 85% revealed the presence of 4 + indican. But 10% of the patients in this class were affected with constipation. The headaches were periodical in character usually accompanied by nausea, often vomiting, bad taste, and general depression. Vertigo and mental sluggishness were frequent complaints—in brief, the symptoms usually ascribed to "intestinal toxemia" or "biliousness." The dietary habits and food discriminations of the patients were studied and finally the following *empiric diet-list* was evolved.

*From the Soper-Mills Clinic.
†This work has been carried out under the supervision of my chief technician, Miss Cornelia Taylor, to whom I am greatly indebted for her faithful and conscientious assistance.
Submitted May 27, 1935.

DIET LIST‡

Breakfast:
Fruit, raw and cooked
Cereals with cream and sugar
Coffee

Lunch:
Choice of all fruits, raw and cooked
All vegetables, raw and cooked
All kinds of breads with butter
Salads—French dressing
Cheese and crackers
Desserts—fruit and fruit ices

Dinner:
Roast, broiled and stewed beef, lamb and fowl
Baked or broiled fish
Potatoes or rice
Choice of green vegetables. Salads
Choice of bread, rolls, muffins and butter
Desserts—fruit and fruit ices

Special caution:
Use sugar sparingly
Use salt in moderation
Eat an excess of fruit and vegetables

It will be observed that eggs and rich desserts particularly egg and milk combinations are excluded from the dietary. This regimen is extremely useful and in many cases brilliant results were secured, however, diminution of the quantity of indican in the urine was a rare occurrence. Many of these patients are benefited by periodic (every two weeks) dose of one to two grains of calomel at bedtime followed in the morning by magnesium sulphate solution. A family history of periodic headaches was secured in the vast majority of these patients. Regulation of colon function and general hygienic supervision such as control of habits, exercise, rest, etc., are valuable adjuncts in the therapy of indicanuria or intestinal toxemia.

The cases of *Duodenal Ulcer* numbered 1320. 60% of these patients had 4 + indican reactions. Dietetic treatment, of course, was exactly the opposite to that advised in the toxic headache patients, the diet consisting largely of milk and egg combinations. The indican was also persistently present despite treatment. Many patients, observed after complete healing of the ulcer, milk and eggs being excluded from the dietary, continued to show a 4 + indicanuria.

As to constipation being a factor, I have records of six cases of megacolon with fecal retention of a week or more, which disclosed but faint traces of indican in the urine. Irregularity of dejections and complaint of gas pressure were the usual features. A majority of these patients employed enemas and cathartics in an effort to secure relief from the subjective symptoms.

Five cases of colectomy for ulcerative colitis and general polyposis were studied. Prior to the operation a 4 + indican was present in the urine of all of these patients. Some months or years later when good restoration of health had occurred, urinalysis failed to disclose a trace of the former large indican content.

Forty-two individuals in good health with no complaint of digestive disorders, headaches or vertigo, were found after a health audit to show 4 + indican reaction in the urine.

TREATMENT

I have employed all the methods suggested by various clinicians and experimentalists, including Bulgarian culture milk, acidophilus milk, Soricin, various intestinal antiseptics, exclusion of meat from the diet, only to abandon them as useless as far as diminution in the indican content of the urine is concerned. These methods also failed to give the patient symptomatic relief. The diet-list given above with periodic doses of calomel and magnesium sulphate has been useful in relieving symptoms. Some patients show a decrease in the indican content after a long course of mineral oil retention enemas. Cases of ulcerative colitis at times reveal a diminution of the indican after prolonged internal use of large doses of bismuth subgallate.

‡The list is of course subject to modification in conformity with requirements of the individual patient.

COMMENT

It is obvious that achlorhydria might inaugurate defective chemical digestive processes that would eventually result in the production of large amounts of indican. The starch granule is not broken up, as noted in the poor chymification of the Ewald-Boas testmeal. The connective tissue from a meat meal may be largely recovered from the feces. Furthermore, more intensive study of the achylia gastrica list of patients disclosed that few of them suffer from the symptoms usually present in the "toxic" headache class.

The large percentage of 4 + indican patients in the duodenal ulcer list presents a problem more difficult to explain. The digestive process is good in duodenal ulcer, and no such defect exists as in achylia gastrica. We must consider that the remaining 40% of the duodenal ulcer patients do not present excess of indican in the urine.

Perhaps the class of patients who remain symptomless regardless of indicanuria are endowed with more stable nervous systems, and develop immunity or resistance against the toxic elements. The larger less-favored class which is susceptible to the toxin, suffer from the toxic headache syndrome and are predisposed to the development of duodenal ulcer.

CONCLUSIONS

1. The term "indican dyscrasia" is employed inasmuch as the evidence indicates an inherited tendency, and its persistence in the individual confirms the view that it is a constitutional disorder.

2. A trace or 1 + indican reaction is rarely absent in any specimen of urine. Therefore, this study includes only the strong 4 + reaction which is termed "indicanuria."

3. Indicanuria may be found in practically all diseases, but is present in a large percentage of patients affected with duodenal ulcer, achylia gastrica, and "toxic" headache.

4. Indicanuria (and such symptoms as may be attributed to it) is amenable to general dietetic and hygienic treatment, but the reaction in the urine remains 4 + regardless of improvement in the patient's condition.

SECTION V—*Therapeutics*

The Pathology and the Treatment of Intestinal Amebiasis*

By

THOMAS T. MACKIE, M.D.
NEW YORK, NEW YORK

IT is a curious fact that a disease which affects from 5% to 10% of the general population should be largely unknown to or ignored by a great proportion of the medical public. Yet this was the case with amebiasis up to the time of the Chicago outbreak. In part this was due to the widespread belief that the disease was restricted to the tropics and the subtropics. In part it resulted from the erroneous conception, created by common nomenclature, that dysentery constitutes one of the outstanding clinical features of the infection. And in part it was the result of the difficulty if not the impossibility of establishing the diagnosis experienced by the untrained observer.

Outside of the southern states it is doubtful if more than a small proportion of practising physicians are aware of the extremely varied clinical pictures which amebiasis may induce. Even when the infection is recognized there is too often a tendency to minimize its importance if acute symptoms are lacking. It is unnecessary to emphasize to anyone familiar with the disease the fallacies of this view. Infestation is invariably associated with tissue damage. Serious complications may arise without antecedent dysentery or even diarrhea. There is a real danger to immediate contacts especially if the infected person be a housewife concerned with the preparation of food for her family (1).

Discussions of treatment, however, frequently are pessimistic concerning eradication of the infection although it is recognized that acute symptoms often may be controlled with relative ease. There is frequent mention of recurrences and so called resistant cases. It is probable that these difficulties may be explained in one of several ways. The results of therapy in endemic areas are necessarily unsatisfactory unless reinfection can be prevented. Knowledge of the detained pathology is too infrequently the basis of the therapeutic plan. Choice of the available amebicidal drugs is not based upon their differing pharmacologic actions.

The not uncommon asymptomatic cyst-passer has created the impression that the *endamoeba histolytica* may exist in the human intestinal tract as a harmless commensal living in symbiosis with the host. Careful pathologic studies, however, have demonstrated the fallacy of this concept. This ameba is invariably a true parasite. Its presence is always associated with actual tissue damage, at the least, localized destruction of the superficial epithelium (2). In the milder cases this may not be evident without the aid of the microscope. In the advanced cases there is extensive and deep ulceration with widespread destruction of the mucosa. Clinically these two extremes represent the symptomless carrier and the serious case of acute amebic dysentery. Between these two pathologic extremes lie the varying degrees of tissue destruction and invasion which are attended by the atypical clinical phenomena which constitute the composite picture of intestinal amebiasis.

The infection is transmitted by the ingestion of the encysted forms in food or drink. These pass through the stomach and upper small intestine to the terminal ileum or colon where excystation occurs and a single four nucleate ameba is released. Subsequent development produces an eight nucleate organism which then divides by fission into eight motile trophozoites each possessing a single nucleus. These motile forms, or trophozoites, then attack the mucous membrane of the intestine, in part by a cytolytic substance which they secrete, and in part by mechanical penetration of their pseudopodia (3). This combined action enables them to destroy the superficial epithelium and to enter the deeper tissues producing the ulceration which constitutes the essential pathology of amebiasis. The lesions are restricted to the colon except in rare instances when the ileo-cecal valve and adjacent ileum may be involved associated with extensive invasion of the cecum. They may occur throughout the colon or be limited to certain areas. The commonest sites in the order of frequency are the cecum, ascending colon, rectum, sigmoid and appendix. When the ulceration is localized, the cecum and ascending colon are much more frequently affected than the rectum or sigmoid (4).

The initial lesion consists of superficial destruction of the mucosa without appreciable invasion of the deeper tissues. This is believed to be due largely to the action of a cytolytic substance secreted by the amebae. At first the amebae lie only on the surface and in the lumens of the glands. The immediately adjacent epithelial cells degenerate, become necrotic, and disappear leaving a denuded stroma. The gland crypts are stripped of their epithelium and in many instances packed with masses of trophozoites. This is accompanied by localized hyperemia but without other

*Presented at the Postgraduate Course in Gastro-intestinal Diseases, Duke University Hospital, Durham, North Carolina, Nov. 1, 1935. Submitted May 2, 1936.

evidence of inflammation. Lesions of this type are almost certainly continually occurring in every carrier of the parasite but rapidly healing if the individual's resistance is effective.

As multiplication of the amebae and progressive epithelial destruction occur, there is invasion of the interglandular tissue and of the submucosa where they are to be found lying singly or in groups. The immediately adjacent tissue is cytolysed and amorphous. There is complete absence of polymorphonuclear infiltration and of signs of suppurative inflammation. Not infrequently lymphatic channels and small veins may be observed containing amebae within their lumens. With penetration into the submucosa, peripheral invasion of normal tissues occurs, progressively increasing the area of necrosis. Thrombosis and destruction of blood vessels impair the nutrition of intact overlying mucous membrane contributing to subsequent ulcer formation. Although the muscular coats of the intestinal wall offer a barrier to the deeper invasion of the amebae, this resistance is relative only. Extension into the muscularis occurs with degeneration and lysis of the muscle fibers, and with the amebae lying singly or in nests throughout the affected zone. Lacking effective resistance on the part of the host, or adequate treatment, the invasion may continue deeper ultimately to reach the peritoneum and to lead to perforation.

The peripheral extension of the infection in the submucosa leads to the formation of a minute abscess cavity roofed by anatomically if not physiologically intact mucous membrane. Rupture of the abscess into the lumen of the intestine then produces the characteristic "flask shaped" ulcer of amebiasis. When these ulcers are numerous and in close apposition, the peripheral invasion of the amebae beneath the mucosa tends to make them confluent and to form the larger open ulcers so commonly encountered in this disease. Microscopic sections taken through such an area present a somewhat different appearance because of the inevitable secondary bacterial infection. Immediately adjacent to the ulcerated area the submucosa is thickened by edema, engorgement of capillaries, lymphocytic infiltration, and proliferation of connective tissue cells. The signs of tissue necrosis become more prominent as the area of ulceration is approached. The nuclei, swollen and pyknotic at the periphery, more centrally have disappeared, and the normal structure of the tissue is destroyed. In the zone of necrosis the amebae are seen scattered or in groups, often lying within veins or capillaries. In areas where bacterial invasion has occurred there are masses of polymorphonuclear leucocytes. The actual walls of such an ulcer are formed by the necrotic or degenerating remnants of the mucosa and submucosa or deeper structures if these have been involved.

Although the essential lesion produced by *endamoeba histolytica* is lysis without suppuration, secondary bacterial infection invariably occurs and may greatly alter the primary pathologic picture. Thus when there has been extensive loss of the mucous membrane there may be many areas where suppurative inflammation with dense collections of leucocytes and even discrete pyogenic abscesses predominate.

Healing of these ulcers occurs from the periphery and, in the case of the smaller ones, is complete and without scar formation. The stimulus to connective tissue proliferation however, results in extensive and often deforming scars at the sites of the larger ulcers.

The gross pathology of the colon varies greatly. All stages from the earliest and most superficial erosion of the mucosa to deep, even perforating, ulcers may occur together. The carrier even in the absence of dysentery or diarrhea may present not only the superficial lesions but deep ulcers as well. The clinical picture which accompanies this infection is not the expression of a particular stage in the pathology. It is the result of the extent of the lesions in the colon together with the effects of secondary bacterial invasion.

In the early preulcerative stage the mucosa presents minute hyperemic and hemorrhagic areas where superficial cytolysis has occurred. The early stages of invasion and lysis of the mucosa and submucosa give rise to minute congested nodular areas projecting from the tops of folds of the mucous membrane. Some of these may show small openings through which a gelatinous fluid may be expressed which contains numbers of the motile forms of trophozoites of endameba histolytica. With deeper and peripheral extension of the necrosis both the opening and the cavity are enlarged to form the typical "flask" ulcer. The surrounding mucosa is congested and hemorrhagic. The edges are ragged usually and the base composed of sloughing necrotic tissue. Certain of the smallest ulcers, however, which are confined to the mucosa may have a punched-out appearance with sharp edges and comparatively smooth and clean bases. These small ulcers are usually round or oval in shape.

The larger ulcers are usually irregular in outline and extend into the muscularis or even deeper. They result from the peripheral extension of the amebae through the submucosa and the coalescing of smaller ulcers to form one large confluent process. These are characteristic in appearance with irregular, raised, shaggy, and undermined edges. In a recent process the floor is composed of necrotic material, pus and blood; in the older ones the floor is relatively clean. The burrowing of the amebae frequently leads to sinus formation beneath the mucosa.

In advanced and serious infections this same characteristic may cause extensive sloughing of the mucosa and serious hemorrhage. It is obvious in such a case that healing must be accompanied by extensive scar tissue formation and permanent deformity of the colon.

The frequent invasion of radicles of the portal system in the intestinal wall indicates one of the routes by which the amebae may reach the liver. With infection of this organ the adjacent hepatic cells undergo cytolysis. Peripheral extension occurs, with surrounding hyperemia, lymphocytic infiltration, hemorrhage, and connective tissue proliferation. At this stage the gross specimen presents small grayish brown moth-eaten areas in which the normal structure has disappeared. The development of true abscess of the liver results from coalescing and extension of many of these small zones of necrosis. Unless bacterial infection has occurred the contents of the cavity are characteristic—a thick grumous material having much the appearance and consistency of anchovy sauce. The connective tissue of the liver is resistant to lysis by the amebae. Condensation of the supporting structure of the organ and new formed connective tissue tend gradually to limit the extension of the necrotic process and to form the dense fibrous wall which is found in the old amebic

liver abscess. Section through such an abscess wall shows an inner zone of more or less cytolysed necrotic material containing amebae, mononuclear cells, fibrin and erythrocytes. Immediately adjoining this is a zone of active connective tissue proliferation infiltrated with lymphocytes, and surrounded by a dense layer of fibrous tissue. The adjacent liver parenchyma is hyperemic and may show capillary hemorrhages.

Study of the pathology of the disease thus demonstrates that the amebae are to be found simultaneously in three different situations. They are present in the colonic contents which they may leave to attack the mucosa. They are present on the surface of the mucous membrane and in the lumens of the glands in the earliest lesions where they destroy the superficial epithelium. In the older lesions they are deeply placed in the tissues of the intestinal wall and not in contact with the intestinal contents. Since this condition presumably exists in the majority of individuals infected by endamoeba histolytica, it is possible to formulate an axiom of therapy. In order to achieve complete eradication of the infection, it is imperative simultaneously to expose the amebae in the intestinal contents, on the surface of the mucosa, and deep within the tissues to lethal concentrations of an actively amebicidal drug.

THERAPY

Some of the numerous therapeutic preparations available are effective in sterilizing the intestinal contents. Others are effective against the amebae in the tissues. However there is no single one which completely fulfills the three fundamental therapeutic indications. This can be accomplished only by combined therapy.

The drugs generally in use for the treatment of amebiasis fall into four groups: the alkaloid of ipecac, emetine and its compounds; organic arsenicals; oxyquinoline derivatives; and compounds of bismuth. Since these vary not only in their pharmacologic actions, but in their usefullness and their dangers, it is desirable to discuss them briefly.

Emetine probably is the most widely known of these drugs. It is used hypodermically as the hydrochloride, and by mouth as the bismuth iodide or the periodide. The latter have no advantages over the hydrochloride. Their use involves the same dangers and in addition they are prone to cause severe nausea and vomiting. Whether given parenterally or by mouth the drug is absorbed and is lethal for the amebae in the tissues. It is excreted slowly by the intestine and the kidney and in consequence too long-continued dosage carries the hazard of cumulative toxic effects. Emetine is a protoplasmic poison which in overdosage acts primarily upon cardiac muscle to produce myocardial degeneration, necrosis and scarring.

Because of its prompt effect in controlling the acute symptoms of amebic dysentery it has enjoyed an undeserved repute in the treatment of intestinal amebiasis. Craig (5) has reported that eighty-five per cent of his cases treated by emetine alone showed continued infection. Yet its direct and efficient action upon the amebae within the tissues makes it one of the most important of all the amebicidal drugs. Because of the dangers of cardiac damage, individual doses of the hydrochloride should not exceed a millogram per kilo of body weight per day, and the total dosage should not be in excess of ten milligrams per kilo. This drug should be used with great caution if at all in the presence of organic heart disease.

Various compounds of arsenic have been widely used. Like emetine they are not completely efficient amebicides. Acute or chronic arsenic poisoning are not rare sequelae. Particularly is this true of stovarsol and treparsol. Recently a less toxic arsenical, carbarsone, has been developed which is more actively amebicidal (6, 7). It is absorbed from the gastrointestinal tract and excreted in the urine. It is administered orally in dosage of 0.25 gm. twice daily for ten days and may be used in 2 per cent solution for retention enemata. This drug is contraindicated in the presence of hepatic and renal disease.

The oxyquinoline derivatives contain approximately 28 per cent of iodine which is excreted in the urine. They are available under a number of trade names, yatren, quinoxyl, anayodin and chinofon (N.N.R.). These preparations have little if any toxicity although they appear to be somewhat irritating to the intestinal tract, in certain individuals increasing or producing diarrhea. This side effect can usually be controlled by rest or by small doses of opium without the necessity for reduction of dosage. They are actively amebicidal (8). However their action seems to be restricted largely to the amebae in the intestinal contents and on the surface of the mucosa since none of them are effective in the case of amebic abscess of the liver. These preparations are supplied as enteric coated pills each of .25 gm. From two to four pills are administered orally three times daily before meals for eight to ten days. They may also be used in 1 per cent of 2.5 per cent solution for retention enemata. The solution should be freshly prepared and not heated since this leads to decomposition of the drug.

A somewhat similar compound, iodochloroxyquinoline, vioform (N.N.R.) contains about 40 per cent of iodine and about 12 per cent of chlorine. It is said to be a more effective amebicide than the other oxyquinoline derivatives (9). Animals killed by a large single dose, however, show some degree of liver necrosis. Consequently this drug should be used with caution when there is evidence of hepatic damage. It is supplied in capsules containing 0.25 gm. each and should be given in two courses of 0.75 gm. daily for ten days with a week's rest between. This compound is irritating to the rectal mucosa and cannot be used for retention enemata.

Various preparations of bismuth have been used in the treatment of amebiasis with the dual objective of eliminating the amebae and of controlling severe diarrhea and dysentery. Their amebicidal activity is low and there is little reason now for their inclusion in the group of specific drugs.

In considering the problem presented by the individual who is infected by *endamoeba histolytica* it has been customary to make an arbitrary distinction between acute dysentery and diarrhea on the one hand and the relatively asymptomatic cyst passer on the other. Different therapeutic measures are discussed for each group as though the principles involved differed fundamentally. Therapeutic failures are too often the result of rule of thumb methods. The known pathology of the disease is ignored. The necessity for simultaneous and effective attack upon the amebae in the intestinal contents, on the surface of the mucous membrane, and in the tissues of the intestinal wall is forgotten. To be efficient, treatment must accomplish

two ends. It must relieve the patient of his immediate symptoms, and even more important it must completely eliminate the infection. If it is recalled that the symptomless cyst passer may have actual ulceration and invasion of the wall of the colon it must be apparent that the carrier and the case of acute dysentery present fundamentally similar problems.

Since no single drug is completely efficient, protozoologic, in contradistinction to clinical, cure necessitates the use of combined treatment. Emetine, which acts primarily upon the amebae in the tissues and little if at all upon those in the intestinal contents, is indispensible, especially during the periods of diarrhea or loose stools. One of the preparations which is little absorbed must be used simultaneously to eliminate the amebae in the contents of the colon and on the surface of the mucous membrane. One of the oxyquinolin derivatives will accomplish this end.

The patient with acute dysentery must be kept strictly in bed. The fluid intake should be large. The diet should be soft or fluid and relatively high in protein and low in carbohydrate. Severe pain, cramps, tenesmus and diarrhea can be controlled by repeated small doses of opium as the camphorated tincture. One milligram per kilo of body weight of emetine hydrochloride is given subcutaneously or intramuscularly each day for eight days. The intravenous route should not be used. During this same period, anayodin or one of the other oxyquinoline derivatives is given in full dosage by mouth. Each morning following a cleansing saline enema eight to ten ounces of a 2 per cent solution is given by rectum and retained as long as the patient is able.* During its administration the foot of the bed should be elevated and the patient should be turned progressively from the back, to the left side, to the back and to the right side to aid distribution of the solution through the colon. Following this period of active treatment proctoscopic examination as well as change in the symptom picture usually indicates healing of the lesions. There is no specific means of treating the secondary bacterial infection. This phase of the problem can only be approached by improving the general nutrition of the patient, correcting anemia by massive dosage of iron or by transfusion if necessary, and by recourse to such other supportive measures as are indicated. Convalesence should be prolonged until both proctoscopic examination and barium enema indicate that healing is complete. (Barium enemata should be employed most cautiously during the "active stage" of the ailment).

The cyst passer whose symptoms are less urgent may be allowed more latitude. (However, it should be remembered that such patient is the one who spreads the disease; prophylosis towards his contacts is here of the greatest significance). A large percentage of these individuals undoubtedly has only superficial lesions in the mucosa without deep invasion by the amebae. The enlarged forms of themselves are capable of causing little or any organic damage. Many of these patients respond to one or more courses of carbarsone or of any of the oxyquinoline preparations. In others, however, subsequent stool examinations indicate continued infection. This must be accepted as presumptive evidence of more extensive lesions and of deeper invasion of the wall of the colon. And it constitutes an indication for recourse to the intensive method of combined treatment.

It is the writer's practice when dealing with the problem of the cyst passer to explain in detail the hazards of the infection and the limitations of ambulatory treatment. If the patient so elects ambulatory treatment is tried, using carbarsone or one of the oxyquinoline drugs by mouth. No limitations of activity are required although the patient is warned against the use of alcohol and cautioned to avoid roughage in the diet. If, however, this approach proves ineffective, the patient is hospitalized for ten days and subjected to combined treatment. This method of dealing with the problem of intestinal amebiasis has given excellent results.

Although amebic abscess of the liver constitutes a large subject by itself, it may not be amiss briefly to refer to certain aspects of treatment. If the pathology is not complicated by bacterial infection, emetine in adequate dosage will sterilize the abscess cavity, prevent its further extension, and destroy viable trophozoides which may be present in other areas of the liver. The problem then resolves itself into the question as to whether or not the patient is able to absorb the necrotic contents of the cavity without further assistance. Falling temperature, diminishing leucocytosis; and progressive diminution in the size of the liver are favorable indications. When the mass of necrotic and cytolysed tissue is too great, removal of the contents by surgical methods is necessary. In the case of a large right lobe abscess simple aspiration of the contents frequently suffices. Needling of the left lobe however is hazardous because of the proximity of the pericardium. When an abscess has become infected by bacteria open operation and drainage are essential.

Whatever the obvious site of infection it cannot be emphasized too strongly that two fundamental objectives must be reached: clinical cure—the patient must be relieved of his symptoms; protozologic cure—the patient must be freed of his amebae. To accomplish these ends the pathologic anatomy must be visualized and the actions of the various available drugs must be understood. To insure effective treatment every patient should be kept under observation for one to two years. During this period careful stool examination must be made on three or four consecutive days every two or three months. The patient may be assured of complete cure only at the end of such a follow-up period during which there has been no indication of persistent infection.

*Many protozoölogists decry the employment of enemata of any nature. Certainly, if an enema be given, one should employ a solution at a temperature of 105°-110° F. after the suggestion of DeRivas, (Univ. of Pennsylvania), whose experiments demonstrated that such temperature is the thermal death point of the protozoa.—Editor.

Pectin as a Detoxication Mechanism**

By

IRA A. MANVILLE, M.D., Ph.D.

ELIZABETH M. BRADWAY, Ph.D.

and

AVOCA S. McMINIS*

PORTLAND, OREGON

PRIOR to 1929, very few attempts had been made to distinguish between *available* carbohydrate which can be utilized and metabolized, and *unavailable* carbohydrate. The former consists of starch and soluble sugars sucrose, glucose and fructose. The latter is composed chiefly of hemicelluloses and fiber or cellulose. While the chief value of the available carbohydrate resides in its coloric equivalent, very little, if any, value, aside from its ability to form bulk, is attributed to the unavailable carbohydrate.

In 1929, the British Medical Research Council made available, through the work of R. A. McCance and R. D. Lawrence, tables giving the available carbohydrate values of many fruits, nuts and vegetables (1). These tables have been further supplemented by Widdowson and McCance (2) and by Bell, Long and Hill (3). While the chief value derived from the efforts of these workers lies in focusing the attention of nutritional workers on direct methods for determining the physiologically available carbohydrate of common edibles, sight should not be lost of possible values other than caloric that may be attributed to other factors resident in the foods eaten. In this connection, it is not the purpose of this report to direct attention to the well-established values of the various vitamins and minerals, but rather, to focus interest upon those carbohydrates, the hemicelluloses and cellulose, which have all too bruskly been put aside as of no value at all except for the possible advantage of bulk.

The medical world is persistently, although somewhat belatedly, attempting to check an all too common overindulgence in such foods as spinach and bran. Attention is being called to the spastic or irritable colon as one of the effects of too much roughage.

Cellulose and cell membranes are popularly supposed to add bulk to the feces by virtue of their indigestibility and thus to counteract constipation by stimulating the wall of the gut to contract. With very high and experimental cellulose diets the bulk of the residue is an important stimulating factor, but with average amounts quantitative considerations show that it can be only of minor importance. The average amount of cellulose, insoluble pentosans and cell membrane eaten daily is about 12 grams (Rubner). Fully half of this material is digested and never reaches the feces. The remainder is insoluble in water and incapable, therefore, of binding water so that this material can only increase the feces by about two per cent, not nearly enough to effect the bulk. Rubner found that a man eating 519 grams of the finest wheat bread excreted feces daily weighing about 120 grams (wet weight). The addition of 50 grams of cell membranes in the form of powdered straw led to an excretion of feces weighing nearly 300 grams, but only 37 grams of these were cell membrane. The rest was made up of cell detritus and products of glandular activity, including water. It is this mixture of substances that caused the increased bulk of the feces. Possible unabsorbed products of fermentative digestion of these cell membranes play a part in the increase.

This stimulation of the intestinal glands is not merely a function of the irritation caused by the insoluble material of the cell membranes. Fruits and vegetables, for example, cause a very large increase of detritus, etc., in feces and yet the cell membranes are relatively well digested and contribute little bulk to the feces. It would seem as though some chemical extract or product of decomposition were the chief stimulant. Very little is known of this subject and it appears to be one on which research might be well repaid. McCance and Lawrence conclude the above discussion by saying, "It is therefore chiefly by virtue of the gland stimulation that cell membranes exert a laxative action. Clinical observation could never have brought out this point, for it could never have differentiated between mere mechanical stimulation leading to increased transit and loose motions of large bulk, and stimulation of the mucus and other glands leading to increased bulk, and this, in turn, to increased transit."

The purpose of this report is to describe experiments which are believed to add more light to the action in the body of certain derivitives of the so-called *unavailable* carbohydrate, namely the hemicelluloses and pectins. In recent years, O'Dwyer (4) and Norris and Schryver (5) have shown that from plant material at least two hemicelluloses can be extracted which, upon hydrolysis, yield glucuronic and galacturonic acid. These two sugar acids exist in combination with the two pentoses, xylose and arabinose. In fact, the latter pentose, arabinose, together with galacturonic acid form the basic part of the pectin molecule. The pectin molecule is now believed to give rise to 8 galacturonic acid molecules. It has been well known for the last fifty years that glycuronic acid plays a very prominent role in the detoxication mechanisms of the body. In the body, it is said never to exist in the free state but in combination in such materials as mucin, chondroitin, heparin (6), etc. It is constantly excreted in normal urine in small amounts conjugated with aromatic alcohols, phenols, ketones, acids, etc.,

Received July 16, 1932

which are either products of metabolic activity, bacterial activity in the body or the presence of various toxic materials in the ingesta. For the last three years in this country and for some ten years prior to this in Germany, raw apple pulp has been used with great success in the treatment of infantile diarrheas and dysenteries. Of the various constitutents of the apple, pectin seemed to be the most logical component to which the greatest part of the therapeutic value could be ascribed. It possesses the properties of a hydrophilic colloid with great adsorptive qualities. Furthermore, it is capable of giving rise to galacturonic acid upon being broken down. The question naturally arose as to whether or not this uronic acid acted similarly to glucuronic acid as a detoxicating mechanism. Malyoth (7) was of the opinion that it would. This report provides evidence that such indeed is the case.

For the purposes of this experiment six rabbits were used. They were so selected that their weights were as nearly identical as possible. They were separated into three groups of two each. Each rabbit was placed in a separate metabolism cage in order that the total urine output could be obtained. For three days the rabbits were fed oatmeal ad libitum. It was hoped by this means to replace foods of variable and uncertain constitution by a food of uniform and known composition. The reason for this was based on preliminary experiments in which it was found impossible or very difficult to deplete rabbits of their glycuronic acid reserves when green foods were ingested. Miller and Conner (8) and Biberfeld (9) also observed that rabbits could tolerate larger doses of menthol if fed greens. The fluid intake was limited to 100 c.c. of Ringer's solution given three times daily by stomach tube. One group of two rabbits received in Ringer's solution one gram of pectin. Beginning with the fourth day, these two rabbits together with two others, were each given one gram of menthol. On the fifth day, the menthol was increased to 1.33 grams, on the sixth day to 1.66 grams and on the seventh day to 2 grams. This provided for a total daily consumption of 3, 4, 5 and 6 grams of menthol.

Each morning the twenty-four hour collection of urine was measured and recorded. Urea and uronic acid determinations were made on aliquot portions. The uronic acid was determined by two methods. One was that described by Bang (10) modified to use the Shaffer-Somogyi copper reagent. The second method was that described by Link (11). Urea was determined colorimetrically by the use of Nessler's reagent. The results of these determinations were recorded as milligrams per rabbit per day. (Table I).

The evidence upon which is based the contention that galacturonic acid (pectin) can be utilized by the organism in detoxicating menthol, is found in the urea and uronic acid excretion. The first day of menthol administration followed a period of three days in which two of the rabbits receiving menthol had been getting also three grams of pectin daily. This provided an opportunity for creating reserves. The results for the first day show that the rabbits receiving pectin in addition to the menthol excreted nearly three times as much uronic acid as the rabbits getting menthol only. The total average excretion of uronic acid by the pectin-fed rabbits was 25 per cent greater than that of the rabbits fed menthol only.

Furthermore the protein breaktown in the pectin-fed rabbits was less, indicating a protein-sparing action on the part of pectin. On the second, third and fourth days, the rabbits receiving menthol only exhibited an increasing protein catabolism while the animals getting the pectin in addition to the menthol showed very little if any variation in the protein breakdown. The rapidly increasing metabolism of endogenous protein in the group receiving menthol only permitted a great increase in uronic acid production, great enough, in fact, to exceed, on the last day only, the uronic acid production of the group getting pectin. In view of these results, the sole source of uronic acid cannot be entirely from the glucogenic amino acids liberated by endogenous protein catabolism. The administration of preformed uronic acid

provides a better source of detoxicating material since it conserves body protein.

A comparison of the average urea excreted by the three groups during the experimental period shows that the groups receiving Ringer's solution only excreted the least. These animals were on a purely starvation basis. The rabbits getting menthol only excreted 75 per cent more urea while those receiving both menthol and pectin were intermediate, excreting only 40 per cent more. A comparison of body weight losses shows the same relationships. Thus both groups getting menthol catabolized more body protein than the group on the starvation basis. Menthol therefore stimulates the breakdown of body protein. This may be taken as an illustration of what is meant by the toxic breakdown of this material. Pectin is able to reduce this effect.

This experiment, which is typical of many, demonstrates the fact that galacturonic acid is capable of forming conjugation products with toxic materials in the same manner as glucuronic acid. In addition, it shows that pectin in as small daily doses as three grams exerts a definite protein-sparing action. This work definitely establishes for the first time the nutritive value of pectin and places additional importance upon those foods which are good sources of this material.

In view of the importance of these findings, it was deemed advisable to determine the reliability of the method used by testing the detoxicating value of chondroitin, a substance containing glucuronic acid as the prosthetic portion of the molecule.

For three days, six rabbits were given two grams of menthol. They were allowed no food. Table II shows that during this period there was a marked decrease in uronic acid output. There was also a gradual increase in protein catabolism. Beginning with the fourth day, four grams of chondroitin was administered along with the menthol. Immediately there resulted a marked increase in uronic acid output and a diminution in protein breakdown. By the second day of chondroitin feeding, diarrhea had become so severe that three of the rabbits died. The experiment was therefore discontinued. There can be no doubt, however, that chondroitin is effective in combating menthol intoxication and that the method employed is capable of conclusively demonstrating this.

As noted above, chondroitin is capable of causing a marked increase in intestinal activity. This was noted by Crandall (12) also. Work in this laboratory with pectin showed that it, too, has marked stimulative properties. In fact, one rabbit died from intestinal gangrene developing as a result of an intussusception involving 10 centimeters of gut. Ivy (13) has noted the laxative influence of mucin. These three materials resemble each other chiefly in their uronic acid components. It does not seem reasonable that the laxative effect is due to the protein fraction. Perhaps the laxative effect of the hemicelluloses and pectins noted previously is due to their uronic acid content.

The rabbits dying from menthol intoxication exhibited gross lesions exclusively limited to the mucosa of the gastro-intestinal tract. Ulcerative and hemorrhagic defects were commonly found in the stomach, duodenum, gall bladder, small and large intestine. The uniform nature and distribution of these lesions is suggestive either of a disturbance of mucin synthesis or an excessive breakdown once it is formed. In either event it appears that the demand for glucuronic acid is so great that the body cannot supply an amount adequate for detoxication purposes and, at the same time maintain a normal gastro-intestinal mucosa.

In this connection, it seems pertinent to add that any defect in the ability of the body to conjugate uronates as, for example, liver injury; any reduction in the intake of preformed uronic acid or an excessive production in the body or introduction into the organism of toxins so that the balance between synthesis and conjugation on the one hand and toxin accumulation on the other is upset, will result in a severe injury to the gastro-intestinal mucosa. In this respect the hemicelluloses and pectins have a nutritive value that is clearly not caloric.

In conclusion it may be said that galacturonic acid plays a role similar to that of glucuronic acid in the detoxication mechanism. Furthermore, sugar acids from preformed sources are of greater value to the organism than those produced by synthesis. Sugar acids from preformed sources are therefore definitely sparing in their function while those produced by synthesis in the body represent a sacrifice of body protein and other essential precursors. It is obvious that such a sacrifice is self-limited. Foods containing hemicellulose and pectin, therefore, have a value separate and distinct from caloric considerations. From the nutritional standpoint, it seems desirable to modify the meaning of the term *unavailable* carbohydrate.

Phenolphthalein Studies*
IV. Phenolphthalein Solubilities†

By

BERNARD FANTUS, M.D.

and

J. M. DYNIEWICZ, Ph.D.

CHICAGO, ILLINOIS

AS "substances do not act unless they are soluble and in solution," the solubility of medicinal substances is of great importance: not only from the standpoint of administration of the medicament to the patient, but also from the standpoint of an understanding of the laws underlying the action of such substances upon living things.

WATER SOLUBILITY

We find that phenolphthalein is soluble at 25° C. in distilled water merely to the extent of 0.3 mgm.-% or 1:333,333, and that it retains this solubility at all degrees of pH-ion concentration from 1.1 up to 8.2. It may well be questioned whether phenolphthalein in this dilution has any biologic effects and experiments are in progress to answer this question.

In order to get more of phenolphthalein into aqueous solution, one may proceed in various ways: one may raise the hydrogen-ion concentration. Crystalline phenolphthalein dissolves at:

pH	*Solubility*
8.8	0.6 mgm.-%
9.0	1.1 mgm.-%
9.2	1.7 mgm.-%
10.0	14.0 mgm.-%

Curve 1 (Graph 1) shows this relation.

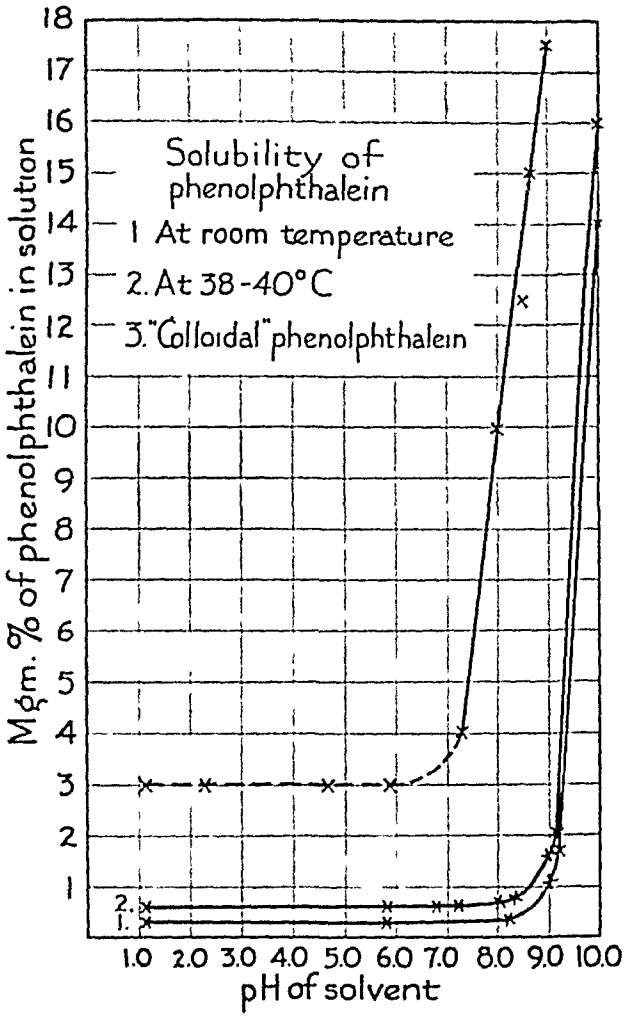
Obviously the soluble sodium phenolphthalein is not formed to any extent from the crystalline phenolphthalein at room temperature until the critical point of pH 9.0 is exceeded.

The following method was employed in the determination of solubility: 25 c.c. of buffer solutions of various degrees of hydrogen-ion concentration were saturated with excess of phenolphthalein by means of prolonged agitation in a shaking machine for several (usually three) hours. The solution was then filtered through a hard filter (Whatman No. 50) and the filtrate estimated for phenolphthalein: using equal volumes of filtrate and N/10 NaOH V.S. for the determination. For comparison we used a standard solution consisting of the same volume of N/10 NaOH and corresponding buffer solution, to which was added a 0.01% phenolphthalein solution to the point of color equality.

In view of the fact that the laxative action of phenolphthalein occurs at body temperature and the influence of temperature on the solubility of phenolphthalein might be of importance, we repeated the study with the buffer solutions of different pH values at a temperature between 38° and 40° C. by keeping them in a constant temperature bath and with occasional agitation after excess of phenolphthalein had been added. Curve 2 (Graph 1) demonstrates the difference, which is very slight (0.6 mgm.-%).

From this it will be seen that crystalline phenolphthalein is only slightly more soluble at body temperature; and it may well be questioned whether a solution of phenolphthalein as dilute as 6 per million has much effect upon living tissue.

"WATER SOLUBILITY" OF COLLOIDAL PHENOLPHTHALEIN



We are therefore faced by a mystery that might possibly be cleared up by the fact that a slightly soluble substance is the more soluble, the greater a surface it presents to the solvent. This raised the question whether there might not be a "colloidal" phenolphthalein of a much higher solubility rate, that might be produced in the bowel, to account for the cathartic action.

We have prepared colloidal phenolphthalein (1) by adding protective colloid (gelatin) to phenolphthalein, freshly precipitated in colloidal form, and find that the solubility of colloidal phenolphthalein is much greater than that of the crystalline variety. This is shown by line 3 (Graph 1) which was obtained in a manner somewhat different from the one that was used in developing curves 1 and 2 (Graph 1). The different procedure was necessary because of the impossibility of filtering the colloidal solution. We therefore estimated the amount of dissolved phenolphthalein by a direct matching of color as compared with an alcoholic standard solution of phenolphthalein added to fluid of the same pH-ion concentration. The broken portion of line 3 indicates that below pH 8.0 there is practically no color. Diffusion experiments (the results of which are represented by the broken line) indicate that a considerably greater amount of colloidal phenolphthalein is in solution than in case of the crystalline form.

The water solubility of phenolphthalein is also raised to a high degree when we add to water drop by drop a dilute (1%) solution of phenolphthalein in alcohol, as is practiced in the use of this substance as an indicator. This process gives the solubility and color reactions we consider characteristic for colloidal phenolphthalein, *i.e.* it strikes a pink color with a solution of sodium bicarbonate at pH 8.0. That we actually have to deal with colloidal phenolphthalein is shown by the fact that, after addition of a few drops of a 1% alcoholic solution of phenolphthalein to water, the pink reaction with sodium bicarbonate solution disappears after standing for a day or two. This is somewhat longer than is the case with colloidal phenolphthalein prepared by saturating a sodium phenol-

Submitted July 29, 1936.

Graph 1.

phthalein solution with CO_2. Perhaps this is because it is in neutral solution without the presence of an ionized salt, which would tend to "salt out" the colloid.

On prolonged (5 days') shaking of phenolphthalein with water (with aid of shaking machine), one secures an opalescent fluid that is richer in phenolphthalein, containing 0.00054 Gm. per 100 c.c.. This fluid cannot be cleared by filtration unless one repeats the filtration many times. That this is merely a fine suspension of microcrystalline and not colloidal phenolphthalein is shown by the fact that it does not give the pink color with sodium bicarbonate. That prolonged shaking has not actually increased the solubility of the phenolphthalein in water is furthermore shown by the fact that it is possible, if one returns the filtrate to the filter often enough to clear the solution; and then the fluid does not contain more than 0.3 mg.-%.

ALCOHOL SOLUBILITY

The solubility of phenolphthalein in alcohol at varying strengths is given in Table I and illustrated by Graph 2.

We see from these that the phenolphthalein solubility increases steadily until we reach a level exceeding 90 per cent by volume; from that point it decreases so that phenolphthalein is less soluble in absolute alcohol than it is in alcohol of official strength. The method employed in these determinations was that recommended by the United States Pharmacopoeia (2).

ALIPHATIC SERIES SOLVENTS

The solubility of phenolphthalein in other fluids of the aliphatic series besides alcohol is given in Table II, from which it will be seen that acetone is approximately three times better a solvent than is alcohol.

This observation seemed to merit special determinations of solubility in acetone-water mixtures of various strengths, which are given in Table III and shown in Graph 3. Here again, as in the case of alcohol, maximum solvent power is reached at 90 per cent, with a curious lessening in higher strength.

While our determination of alcohol solubility agrees with the U.S.P. figure, which is given at 1 Gm. in 12 (total of 13 c.c. of saturated solution containing 1 Gm. of phenolphthalein as shown in Table I), the figure for ether solubility which is given at 1 Gm. in 70 is one that we can not duplicate. We find it more nearly 1 Gm. in 100 (Table II). The slight solubility of phenolphthalein in chloroform and carbon tetrachloride is rather interesting. It is also remarkable that petroleum benzin and liquid petrolatum dissolve only 0.5 mgm.-%—not much more than does water.

AROMATIC SERIES SOLVENTS

The solvents of the aromatic series are rather low in potency, although the least efficient of those we studied —xylene—is five times a better solvent than water, which accounts for the fact that when xylene is employed for the preservation of urine, practically all of the phenolphthalein is found in the xylene layer.

OIL SOLUBILITY

The literature regarding the solubility of phenolphthalein in oils seems to be in an unsatisfactory condition, as well as methods for the determination thereof. After consultation with Dr. L. E. Warren, Senior Chemist, U. S. Department of Agriculture, we developed the following method:

A. Gravimetric method for determination of oil dissolved phenolphthalein. Place 5 c.c. of the saturated oil in a separatory funnel, add 20 c.c. of 0.1% solution of sodium hydroxide, separate the "soap" formed by the addition of 5 Gm. of sodium chloride. Transfer the alkaline solution containing the phenol-

tared weighing bottle, evaporate the ether and dry to constant weight. Since a small portion of the oil is carried through the process of extraction, a 5 c.c. portion of the oil used as the solvent is treated in exactly the same way (blank determination). The difference in weight of the two determinations represents the amount of phenolphthalein in 5 c.c. of the oil.

B. Colorimetric method for determination of phenolphthalein in oils. Since the procedure in the gravimetric method for the determination of phenolphthalein in oils is rather involved, and a check on results was desired, a colorimetric method was considered. Four colorimetric procedures were used, the final selection of the method depending upon the solubility of the oil.

Method B-1. Olive oil. Measure accurately 5 c.c. of oil saturated with phenolphthalein into a 100 c.c. glass cylinder; add 70 c.c. of ether and 25 c.c. of alcoholic KOH N 200. At the same time prepare a standard for comparison consisting of 5 c.c. of the same kind of oil used to dissolve the phenolphthalein, 70 c.c. of ether, and 25 c.c. of alcoholic KOH N/200. With a pipette graduated in hundredths of a c.c., add to this a standard solution of phenolphthalein (0.100 Gm. per 100 c.c.) until color equality, final reading being made with the aid of a colorimeter. From the amount of phenolphthalein required to produce the same color, the weight of phenolphthalein dissolved in the oil is calculated.

For expressed oil of almond, use 10 c.c. N 10 KOH instead of N 200 KOH. Otherwise proceed as above.

Method B-2. For oils practically insoluble in alcohol: cod liver oil, cotton seed oil, liquid petrolatum, or corn oil. Extract 5 c.c. of phenolphthalein saturated oil, measured accurately, with 25 c.c. portions of alcohol until the phenolphthalein is dissolved out, as shown by the fact that no color is obtained with alkali (three extractions usually suffice). Filter the alcoholic solutions through a hard filter. Prepare standard at the same time by extracting 5 c.c. of the same kind of oil used for solubility determination, to the same volume, with alcohol. Add 10 c.c. of alcoholic N/10 KOH to each cylinder and alcoholic standard phenolphthalein solution (0.100 Gm. per 100 c.c.) until color equality. Final reading with aid of colorimeter. Calculate.

Method B-3. For oils soluble in alcohol, such as castor oil. Add 5 c.c. of oil accurately measured to a 100 c.c. glass cylinder; add 85 c.c. of alcohol and 10 c.c. of alcoholic N/10 KOH V.S. Standard consists of 5 c.c. of same kind of oil used for determination, 85 c.c. of alcohol and 10 c.c. of the alcoholic N/10 KOH, and standard phenolphthalein solution (0.100 Gm. per 100 c.c.) measured accurately, to color equality.

Method B-4. Cod liver oil, etc. Place 5 c.c. of the saturated oil in a separatory funnel; add 20 c.c. of a 0.1% solution of sodium hydroxide, separate the "soap" formed by the addition of 5 Gm. of sodium chloride. Filter the solution and collect the filtrate in a 100 c.c. graduated glass cylinder. Continue the extraction of the oil with 15 c.c. portions of 0.05% NaOH and 5 Gm. additions of NaCl until the phenolphthalein is completely extracted. At the same time run a "blank" determination to be used as a standard for comparison, consisting of 5 c.c. of the same oil used for the solubility determination, extracting with exactly the same amounts of NaOH and using the same amount of NaCl. Make both solutions up to the same volume and add a standard phenolphthalein solution (0.100 Gm. per 100 c.c.) to the "blank" until color equality. Calculate amount of phenolphthalein in the oil.

In all of the colorimetric determinations, the reading of color should be made as quickly as possible, as a change in color may result.

Method of Saturating Oils with Phenolphthalein. To determine the solubility of phenolphthalein in oils, we saturate oil with phenolphthalein (1.0 Gm. per 100 c.c. oil) at room temperature (20-28° C.) for several days with occasional agitation, then in constant temperature bath at 25° C. for three hours with constant agitation. Filter at a temperature as near 25° C. as possible. Talc is used to facilitate clear filtering of the oils which did not filter clear.

The results are shown in Table IV, from which it will be seen that castor oil is by far the best among the oily solvents: dissolving ½ Gm. per 100 c.c.. All the other oils tested are poor solvents with relatively little difference among them. Liquid petrolatum, which is not of course a true oil, is as was previously mentioned the poorest solvent of them all. It will be seen from Table IV, that the alcohol solubility of the oils is

TABLE IV

Solubility of phenolphthalein in oils

	Grams of Phthn. Dissolved by 100 c.c.	Alcohol Solubility of Oil
Castor Oil	0.500	miscible
Cod Liver Oil, dark amber	0.032	0.325
Cotton Seed Oil	0.022	0.0878
Expressed Oil Almond	0.020	0.0628
Corn Oil	0.019	0.0566
Cod Liver Oil, light amber	0.016	0.1612
Olive Oil	0.014	0.071
Liquid Petrolatum	0.0035	0.011

not proportionate to their ability to dissolve phenolphthalein; hence is of no value in explaining the difference in the solvent power of the oils.

That alcohol solubility may be of some significance however is shown in our experience with two different kinds of cod liver oil, given in Table IV.

	Gm. of Phthn. Dissolved by 100 c.c.	Alcohol Solubility in cil	Saponification Value
Cod liver oil, dark amber	0.032	0.3250	210.5
Cod liver oil, light amber	0.016	0.1612	184.6

The fact that the dark amber cod liver oil dissolved twice as much phenolphthalein as the light amber and that it is also twice as alcohol-soluble as the light may possibly be significant. The saponification value shows no proportionate relation.

CONCLUSIONS

1. Phenolphthalein is almost insoluble in water or buffer solutions up to pH 9.0, even at body temperature.
2. Colloidal phenolphthalein is considerably more soluble and at a lower hydrogen-ion concentration, being capable of producing the pink sodium phenolphthalein with $NaHCO_3$ solution of pH 8.0-8.2.
3. The solubility in alcohol increases with increase in strength of alcohol water mixtures up to that of the U.S.P. official alcohol. It is slightly less in absolute alcohol.
4. The liquids of the aliphatic series are in general better solvents for phenolphthalein than are those of the aromatic series. Notable exceptions to this proposition are carbon tetrachloride and the petroleum products which are very poor solvents.
5. Phenolphthalein is, in general, but poorly dissolved by oil with the exception of castor oil, which is capable of dissolving as much as ½% of phenolphthalein.

Bile Salt Therapy in Liver and Gall Bladder Disease*

By

BERNARD D. ROSENAK, M.D.

and

KENNETH G. KOHLSTAEDT, M.D.

INDIANAPOLIS, INDIANA

WHENEVER the management of a case of liver or gall bladder disease is undertaken one must balance the prospects of satisfactory results from surgical treatment against those to be expected from a carefully conducted medical regime.

There is abundant literature regarding the results of gall bladder surgery and there is for the most part little discrepancy in the findings. Judd (1), in analyzing the results of cholecystectomy upon the basis of pathologic changes in the gall bladder, found that when these changes were minimal the results were satisfactory in 64 per cent of the cases, and when cholecystitis and stones were found they were satisfactory in 87.8 per cent. However, in cases of noncalculous cholecystitis, Graham and Mackey (2) reported satisfactory results in only 30 per cent of the cases and improvement in another 30 per cent in which cholecystectomy had been done.

It is evident from these reports as well as from the results of other investigators that only in the presence of severe symptoms (such as colic) associated with gall stones will removal of the gall bladder give satisfac-

*From the Medical Clinic of the Indianapolis City Hospital.
Submitted June 25, 1936.

tory results in a large percentage of the cases. Even in many of these, subsequent investigation will reveal that, although entirely relieved from pain, these patients continue to suffer from indigestion, food intolerance, and constipation.

Unfortunately reports of the follow-up studies of large groups of gall bladder cases treated medically are extremely rare. Blackford, King and Sherwood (3) recently reported a group of 200 unoperated cases of gall bladder disease. Based upon an eight year follow-up period they found that 37 per cent of the patients with proved cholecystitis were living and had been relieved to a satisfactory extent by a plan of treatment which included careful restriction of diet, removal of foci of infection, and the use of mild saline cathartics.

The employment of cholagogic drugs in the treatment of liver and gall bladder disease has always been regarded as a very valuable and logical approach to the medical treatment of these cases. In a theoretical consideration of the metabolism of the bile acids (4), one finds many factors which support the rationale of their use in the medical management of gall bladder disease.

It is a well known fact that the bile acids are manufactured in the liver from protein substances in the food and from protein decomposition products produced by the breakdown of the body tissues. Whipple and his co-workers (5) have shown that tryptophane is the most important precursor of the bile acids.

The functions of the bile acids after they reach the intestinal tract are well known. They aid in the digestion and absorption of the fats; they have been shown to stimulate the flow of pancreatic enzymes; they seem to have a tonic effect upon the intestinal motility.

A unique feature of the metabolism of the bile acids is the manner in which a fraction of the total bile acid secreted is reabsorbed from the intestine and carried back to the liver. Within the liver the bile acids are thought to act as the chief stimulant to the hepatic cells in causing the production of additional quantities of the bile acids. However, at the present time little is known of the intra-hepatic regulatory mechanism which controls the secretion or destruction of the bile salts within the liver.

Another important rôle ascribed to the bile acids by both Wright and Whipple (5), and Andrews and his associates (6) is the relation of the bile acids to the metabolism of cholesterol. It has been shown that cholesterol tends to precipitate out of the bile in which the bile acid content has been reduced. Many see in this phenomenon a possible explanation for the formation of gall stones. Further studies have shown that infections of the biliary tract may cause a reabsorption of the bile salts from the gall bladder thus reducing their concentration in the bile and thereby influencing the precipitation of cholesterol. Infections in other parts of the body and pregnancy have also been shown to have a similar effect upon the bile acid concentration. Thus it may eventually be found that the bile salt—cholesterol ratio is a very important factor in the etiology of cholelithiasis.

In reviewing the accepted plans of medical treatment of gall bladder disease it is apparent that, although most writers mention the use of bile salt preparations, bile salt therapy has not been very successful in this country, and only a few detailed studies are available. The explanation of this lack of success is that the preparations used have consisted of the least active and the most toxic of the bile salts. For this reason the dosage has been too small to produce any real benefits, and it has been necessary to fortify most preparations with cathartics in order to produce any demonstrable effect upon the constipation which commonly occurs in this group of patients. Neubauer (7) has shown that dehydrocholic (desoxycholic) acid has the strongest cholagogic and choleretic activity of any of the bile acids and is at the same time the least toxic. A few German (7) and American clinicians (8) have given dehydrocholic acid and its sodium salt considerable trial, but the use of the more effective forms of bile salts without fortification with other drugs has been generally neglected. In view of these facts we have attempted to test the clinical value of a bile salt preparation† containing a high percentage of desoxycholic acid.

Patients were referred for this study from the General Medicine Clinic of the Indianapolis City Hospital and were treated for the most part as out-patients. All patients were placed on the same diet, one in which there was a definite fat restriction with moderate carbohydrate and high protein content. Coöperation concerning diet was poor inasmuch as many of the dispensary patients were either on relief or on strictly limited incomes. A number of apparent failures and recurrences could be definitely ascribed to dietary indiscretion. Fifteen patients seen in private practice are included in this group, and in these cases better coöperation is reflected in more satisfactory response to treatment.

The bile salt preparation was administered in 5 grain capsules. These were given before or during meals. Patients were started on one capsule three times daily, and the dose was increased until regular bowel movements were obtained without taking any cathartics. One patient required 75 grains a day for several days before the bowels began to move. No untoward symptoms developed and the dose was gradually reduced. Most patients found the optimum dose to be two to three capsules three times daily. A number of patients complained that the stools were quite loose and that there was some abdominal pain at first. In most instances this quickly disappeared, and the patients stated that the bowels moved regularly once or twice daily, usually soon after meals, and that the stools were soft, formed, and very dark in color. In several cases the benefits of this treatment seemed to be enhanced by the addition of tincture of belladonna in the usual doses.

RESULTS

A group of 63 patients was treated with bile salts over a period of nine months. For purposes of discussion we have divided these cases into three divisions.

The first group is composed of 22 cases of cholelithiasis. In these patients gall stones were definitely demonstrated either by X-ray study or palpation at time of surgery or by finding cholesterol crystals in the bile of patients with a nonvisualizing gall bladder. Frequent attacks of colic, intolerance to fat or fried foods, and chronic constipation with flatulance were

†Bilron (Iron Bile Salts, Lilly) supplied through the courtesy of Eli Lilly and Company.

characteristic findings which occurred in all of these cases.

The results obtained in this type of patient by the method of treatment as previously outlined are shown in Table I. It is evident that in the majority of cases pain was not satisfactorily removed by this medical treatment. However, better results were obtained in relief of constipation and digestive symptoms. In all patients with definitely proved cholelithiasis who were

TABLE I

Results of treatment in 22 cases of proved cholelithiasis

	Relieved	Improved	Unimproved
Pain	10	2	10
Food intolerance and indigestion	11	6	3
Constipation	15	4	1

Résumé of clinical findings:
Jaundice in 11 cases
Typical attacks of colic in 22 cases
Gastro-intestinal disturbances in 20 cases
Cholecystograms—positive (shadow of stones seen) in 13 cases
—negative, plus cholesterol crystals in bile in 2 cases

suitable surgical risks we have recommended surgery. Seven of these patients have been operated on at the present time.

The second group is composed of 16 patients with cholecystitis without proof of the presence of stones. In all of these patients attacks of colic, digestive disturbances with food intolerance, and constipation had occurred, but X-ray findings and laboratory studies did not offer definite proof of the presence of gall stones. The results are given in Table II. The treatment was more successful in these patients. Pain was entirely relieved in a large proportion of them, and the marked improvement of digestive symptoms in all was most striking. These results compare satisfactorily with those obtained in this type of patient with surgical treatment.

The third group is made up of 25 patients with symptoms indicative of gall bladder dysfunction but in whom positive evidence of actual disease of the gall bladder may be lacking. It is difficult to definitely classify all of these patients. In some, indigestion and constipation of the type ascribed to hepatic insufficiency may be the only evidence of pathology. Pain is very indefinite or may be completely absent. True colic with subscapular radiation does not occur. The stools are characteristically light yellow. Headaches, vertigo, nausea and vomiting are the symptoms which complete this syndrome. The mechanism which is capable of producing this syndrome is not known at the present time, but it is apparent that there is some relation to hepatic insufficiency, although it may be impossible to demonstrate this hepatic failure by any of the ordinary liver function tests.

TABLE II

Results of treatment in 16 cases of cholecystitis in which the presence of gall stones could not be proved

	Entirely Free	Improved	Unimproved
Pain	5	8	3
Constipation	11	2	
Indigestion	6	10	

Résumé of clinical findings:
Jaundice in 4 cases
Attacks of colic in 7 cases
Gastro-intestinal disturbances in all cases
Cholecystograms—nonvisualized in 11 cases
—faintly visualized with *failure to empty in 20 hours* in 5 cases

Very satisfactory results were obtained in this group (Table III). Furthermore, when bile salts were discontinued temporarily in these patients, all symptoms returned and similar results could not be obtained by means of dietary control alone or by means of cathartics.

In this group of patients we would frequently find "gall bladder disease" given as the diagnosis, but without definite pathology to be found in the gall bladder at surgery. As the experience of most physicians will

TABLE III

Results of treatment in a miscellaneous group of 25 cases of functional biliary and hepatic disturbances

		Entirely Free	Improved	Unimproved
Pain	Definite (14 cases)	8	4	2
	Indefinite (6 cases)	6	—	—
Indigestion		22	2	1
Constipation		22	2	1

Résumé of clinical findings:
Jaundice absent in all cases
Attacks of colic absent in all cases
Pain { definite upper right quadrant in 14 cases; vague, generalized abdominal pain in 6 cases; no history of any pain in 5 cases
Cholecystograms { normal in 10 cases; failed to visualize or faintly visualized in 12 cases

bear out, surgery will not alleviate these symptoms, and it is in these patients also that we find the largest proportion of recurrence of symptoms postoperatively.

CONCLUSIONS

1. Results of surgical treatment of patients with symptoms of biliary tract disease, but who do not have gall stones or attacks of biliary colic, are frequently unsatisfactory.

2. In this series of cases marked benefits were obtained by a plan of medical treatment consisting of a low fat diet and the administration of a pure bile salt preparation having high concentration of desoxycholic acid. The most marked improvement was seen in the control of digestive symptoms and constipation.

3. Less satisfactory results were obtained in patients with cholelithiasis than in the noncalculous cholecystitis group. The best results occurred in the miscellaneous group consisting of persons with hepatic insufficiency, biliary dyskinesia, and other functional disorders of the liver in which the secretory mechanism seemed to be sluggish.

SECTION VII—*Surgery of the Lower Colon and Rectum*

Clinical and Therapeutic Status of Cases of Colonic Diverticulosis Seen in Office Practice*

By

J. H. WILLARD, M.D.

and

H. L. BOCKUS, M.D.

PHILADELPHIA, PENNSYLVANIA

AN analysis has been made of 72 cases of diverticulosis found in a survey of the authors' office records. Patients seen initially in the hospital and *home have been purposely excluded in order to present* a statistical study of office material. This type of study should give a more accurate idea of the incidence of the abnormality, frequency of symptoms and of complications than previously reported series of cases collected from both ambulant and hospital sources. It *is the nearest approach to a survey of a cross section* of the population who do not seek medical aid.

Incidence. Thirty-eight of these cases were found in making a study of 463 consecutive cases upon whom barium enemas were carried out, giving an incidence of 8.2 per cent. These figures approximate those of Ochsner and Bargen, who found colonic diverticula in 7 per cent of 2,747 patients examined roentgenologically, and those of Spriggs and Marxer, who reported diverticula or pre-diverticulosis in 100 of 1,000 patients examined.

A comparison is made between functional colopathies and diverticulosis (Fig. 1). Fifty-three per cent of our office cases showed some type of functional colonic abnormality, whereas diverticula occurred in the colon in only 8.2 per cent. This tends to refute any argument which might be advanced that diverticula are more prone to develop in colons which are the seat of a neuromuscular irritability. A racial factor is of interest in this connection. Thirty per cent of the patients with functional abnormalities, largely "irritable" colon, were Jewish while only 13 per cent of those with diverticulosis were of this race.

Age and Sex. The age distribution of these two groups of office patients are shown graphically in Figure 1. The number of patients encountered with the so-called "irritable" colon diminishes gradually after age 35, whereas there is a steady increase in diverticulosis after this age. Seventy-two per cent of the latter were over 50 years of age, the average age of the group being 55.4 years. The youngest patient was thirty and the oldest 81 years of age. These figures simulate those of Ochsner and Bargen and of Spriggs and Marxer. There were no patients under 30 years of age in either of these two series. There was practically no difference in the sex distribution of our cases, 34 were male and 38 female. The age averaged the same in the two sexes.

Constitutional Habitus and Obesity. In this group 43 patients were classified as normal or sthenic habitus, 12 hypersthenic and 17 asthenic. There seems to be no predilection for any particular habitus, although the incidence of diverticulosis in those of asthenic build (23.6 per cent) is somewhat less than the occurrence of this habitus in office patients. Some credence has been given to the theory that obesity may encourage the development of colonic diverticula. Thirty-three patients, or 46 per cent, of the group either were obese (21) or had been overweight in the

*Read at the Annual Session of the American Proctologic Society, Kansas City, Mo., 1934.
Received for publication July 23, 1934.

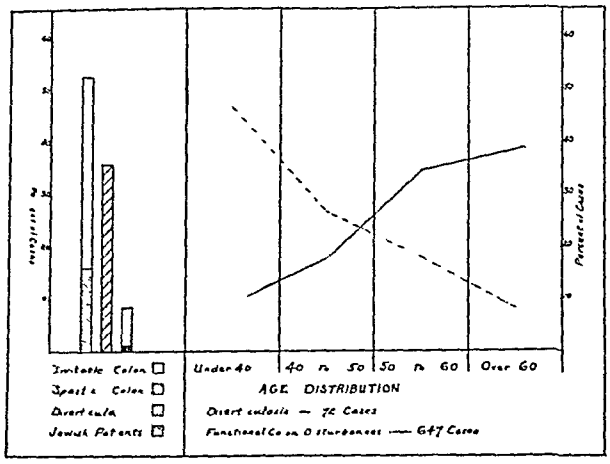

Fig. 1. Comparison of incidence (occurrence in Jewish patients) and age distribution of cases of "irritable" colon with cases of diverticulosis.

past. This incidence of obesity is somewhat higher than expectancy in office cases

Bowel Habit. Many writers have stressed the importance of constipation as a predisposing factor in the development of colonic diverticula The data relating to previous habits of defecation in this group are significant as particular attention was devoted to this question in the taking of the histories. Hospital records are frequently incomplete in this regard. It was found that only 32 patients or 44 per cent had been chronically constipated, 29 per cent of these having had the condition for more than 10 years. Ten of the group with constipation had had attacks of diarrhea. Twenty-nine patients or 41 per cent of the cases

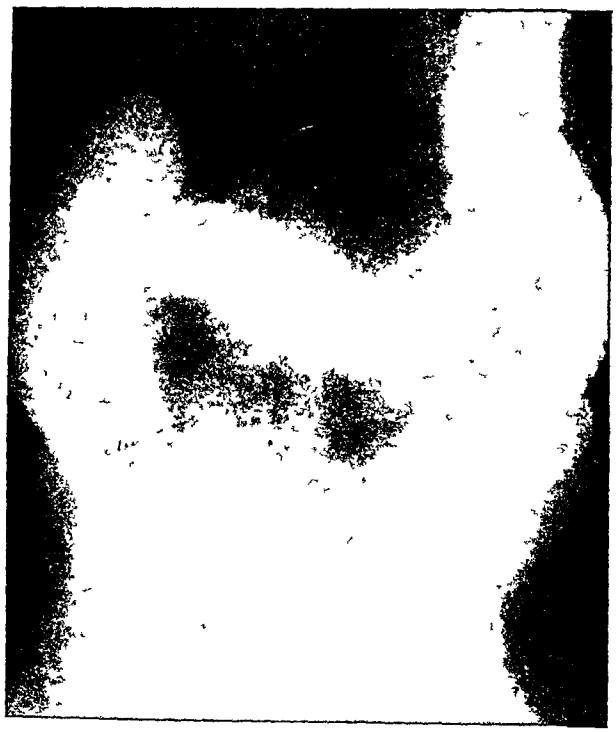

Fig. 2. Showing a few diverticula in the descending and pelvic segments protruding from the outline of the completely filled colon.

Fig. 3. Same patient as Fig. 2 showing innumerable diverticula scattered throughout the descending colon after evacuation of the barium enema.

gave a history of normal bowel habit, ten of whom occasionally complained of diarrhea. A persistent tendency toward diarrhea alone was noted in 11 patients or 15 per cent of the entire series. This incidence of constipation in the entire group is less than

Fig. 4. Showing sizeable filling defect in patient with a palpable tumor following an attack of diverticulitis.

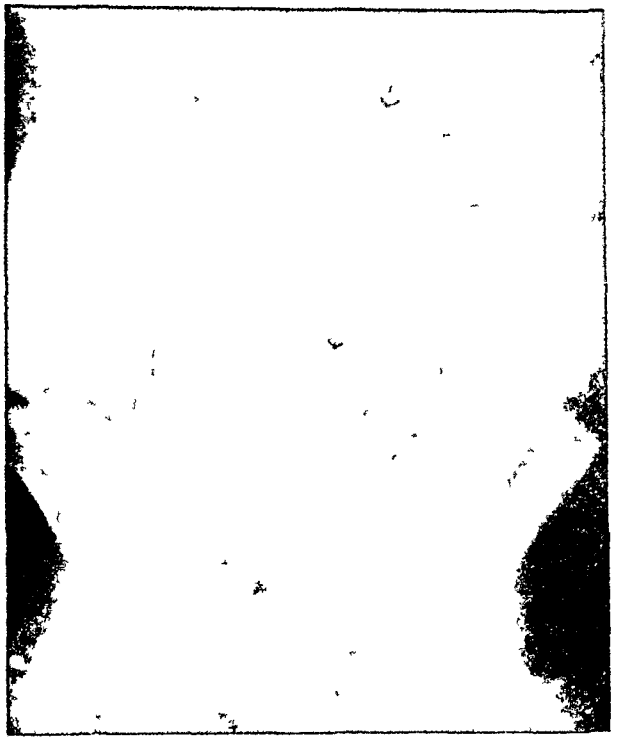

Fig. 5. Triangular incisura-like defect in pelvic and transverse segments of colon in patient with history of several severe attacks of diverticulitis simulating partial obstruction.

Fig. 6. Illustrating the deep incisura like defect in the pelvic colon in a patient with history of attacks of diverticulitis.

that for admissions to the office for all causes (56 per cent). The occurrence of constipation in our practice does not steadily increase with age as does the age distribution of diverticulosis. Therefore, it seems doubtful if constipation per se is an important predisposing cause of diverticulosis. We have seen diverticulosis in a number of patients, who gave a history suggestive of an active gastrocolic reflex, *i.e.*, a life-long tendency to defecate after meals or excitement.

Diagnosis. Ochsner and Bargen report finding diverticular sacculation, fixation of the sigmoid or actual diverticula in 15 of 72 patients subjected to sigmoidoscopy. A positive sigmoidoscopic diagnosis can only be made by actually visualizing the diverticula, and the above mentioned authors did not specifically record this finding in their cases. We failed to

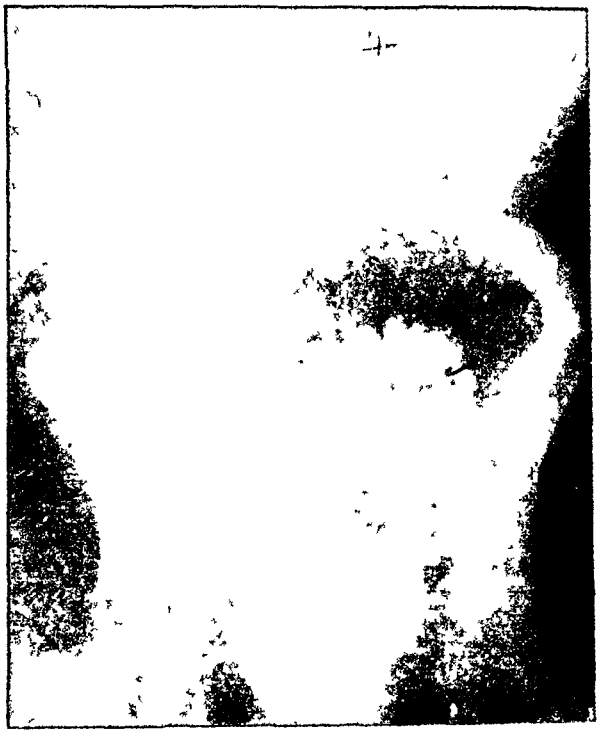

Fig. 7. Suggestion of same appearance in the pelvic colon. There is a diverticulum projecting from both sides of the deep incisura like defects.

demonstrate a diverticulum in 46 patients who were examined, and we have actually seen but one diverticulum through the sigmoidoscope in the past 10 years. The failure to see the pouches sigmoidoscopically is due primarily to their location above the reach of the ordinary 10 inch sigmoidoscope. In some instances it may be due to difficulty in distending the upper sigmoid because of spasm, and in others to sharp angulation and deep mucosal folds. The diagnosis must depend primarily upon the roentgenological examination of the colon. The technique of methods of demonstration of diverticula has been well presented by Case and Spriggs and Marxer and need not be dwelled upon here. Figs. 2 and 3 illustrate the superiority of the film taken after evacuation of the opaque enema as compared with the "filled colon" film. Diverticula are frequently completely obscured by complete filling of the colon with barium.

Other Diverticula. Duodenal diverticula were demonstrated in 4 cases and suspected in 2 more. In all but one, a duodenal ulcer syndrome was present. A small diverticulum was seen in the terminal ileum in one case and suspected in 4 others. Small diverticula in the terminal ileum undoubtedly escape diagnosis in many instances.

Clinical Status. General recognition is accorded frank attacks of diverticulitis, but there exists a generally accepted belief that diverticulosis is very often asymptomatic. Spriggs and Marxer could find no symptoms referable to the condition in one-third of their cases. In many instances, it is exceedingly difficult to determine accurately the part played by the diverticula in the initiation of certain symptoms. Table I lists the chief complaints on admission in the order of their frequency. Diarrhea, heading the list with 18 patients (21 per cent), occurred more fre-

	4 Cases	Symptoms in 2	
Diarrhea	1 Case		
Bleeding (Occult)	1 Case		

quently than in any series of cases reported previously. The percentage of patients with diarrhea either on admission or in the past was much higher (45 per cent). Excluding the emotional factor, no other cause for diarrhea was found except in four patients who had an achlorhydria. Constipation was the chief complaint in 13 cases, but in most instances it had been present more than 10 years and must have antedated the development of diverticula quite frequently. Other complaints which may have depended in some measure upon diverticulosis were flatulence occurring 9 times, abdominal pain and distress in various locations 24 times, and bloody stools 3 times. We feel confident that many bouts of slight abdominal distress and irregular bowel habit, often following the ingestion of large amounts of roughage or excessive physical exercise or long automobile rides, are dependent upon irritation of colonic diverticula. A careful history in many individuals with diverticulosis will reveal such attacks of varying severity in the past. They usually go undiagnosed unless a severe attack of diverticulitis develops. The same clinical picture in younger patients is more often dependent upon a so-called "irritable" or "unstable" colon. Excluding constipation, symptoms which may have depended upon diverticulosis in this series occurred in 54 cases or 75 per cent.

Another method of attempting to ascertain the clinical significance of diverticulosis in this series is afforded by an analysis of the chief diagnoses (Table II). It will be noted that diverticulosis or diverticulitis was entered as one of the major diagnoses in 46 cases or 64 per cent. Allowing for the personal equation, these data suggest that well over 50 per cent of patients with diverticulosis visiting the office of a gastro-enterologist have symptoms dependent upon this condition. It is highly probable that many of the remaining patients have had symptoms in the past attributable to slight irritation of diverticula.

Relationship of Symptoms to the Number, Location and Size of Diverticula. Table III denotes statistical data relating to location, size and number of diverticula which does not differ materially from similar statistics published elsewhere. By consulting Table IV, it will be noted that the incidence of symptoms collectively did not depend upon the number of diverticula found. However, the occurrence of symptoms thought to be due to diverticulitis was almost twice as great in the cases with many pouches as those with few. The incidence of bleeding was much greater in the group with few diverticula, but in some of these patients the bleeding was probably from some other source.

In Table V, the symptomatology in relation to the site of the diverticula is given. There was no essential difference in the incidence of symptoms occurring in cases with diverticula confined to the pelvic colon and those with pouches throughout the left colon. However, complaints which were attributed to diverticulitis occurred three times more often in patients with diverticula of the entire left colon as compared with those with pouches in the pelvic colon only. The few patients with involvement of the entire colon all presented symptoms thought to be due to the diverticula.

The incidence of pertinent symptoms increased steadily as the recorded size of the diverticula increased (Table VI). The occurrence of diarrhea, diverticulitis and bleeding was consistently greater in patients with large pouches than in those with smaller diverticula.

DIVERTICULITIS

In 16 cases or 22 per cent of the entire group attacks suggestive of diverticulitis had occurred in the past or appeared during observation. Ochsner and Bargen report a comparable incidence of diverticulitis in 27 per cent of cases. Twelve of our patients were men. The average age and age range was identical with the entire diverticulosis group. We have previously noted that the occurrence of "diverticulitis" symptoms is much greater in patients with many diverticula. Likewise the larger pouches seem more prone to be associated with symptoms of this type. Pain, the outstanding symptom in diverticulitis, occurred in 14 patients or 87.5 per cent. In all but three, the pain was located somewhere in the left or lower abdomen, most commonly in the lower left quadrant. Fever was associated with attacks in 6 cases (37 per cent), hematuria in 1 case and gross hemorrhage from the bowel in 1 case. Two cases were examples of the hyperplastic type, having a palpable tumor and symptoms of partial obstruction. Fig. 4 shows the roentgen defect in one of these cases when first seen two months after an attack of diverticulitis. The defect has gradually diminished in size during a period of observation of more than one year. The second case with a similar history has been followed for three months. Both have remained symptom-free, the stools have been persistently negative for occult blood and considerable weight gain has taken place. The tumor in both patients has become smaller, probably due to subsidence of the inflammatory reaction and absence of inspissated feces proximal to the partial obstruction. A differentiation from malignancy is frequently impossible in cases of this type, but diverticulitis is suggested by the "inflammatory" feel of the mass, the appearance of zonal spasm by X-ray without evidence of an actual encroaching defect, the absence of weight loss, rapid clearing up of symptoms and disappearance

TABLE VI

Relationship of symptoms to size of diverticula

Small:	50 Cases	Symptoms in 26	52 per cent
Diarrhea	20 Cases	40 per cent	
Diverticulitis	10 Cases	20 per cent	
Bleeding:	5 Cases	10 per cent	
Gross	2 Cases	4 per cent	
Occult	3 Cases	6 per cent	
Variable or Moderate:	15 Cases	Symptoms in 9	60 per cent
Diarrhea	7 Cases	49 per cent	
Diverticulitis	4 Cases	24 per cent	
Bleeding:	5 Cases	33 per cent	
Gross	3 Cases	27 per cent	
Occult	2 Cases	6 per cent	
Large:	7 Cases	Symptoms in 7	100 per cent
Diarrhea	6 Cases	86 per cent	
Diverticulitis	2 Cases	30 per cent	
Bleeding (Occult)	2 Cases	30 per cent	

of occult blood from the stools. The sigmoidoscope may help. Most cancers of the left colon are within reach of the sigmoidoscope, and there is only rarely sufficient spasm or edema below the growth to prevent its visualization. In diverticulitis causing trouble low down, the instrument comes on bowel lumen closed by edema and spasm and gives a sensation of fixation *without demonstrating a mass. The bowel habit in* these patients with diverticulitis was on the side of frequency, diarrhea was present in 10, constipation in 3 and the function was unchanged in 3 cases.

We should like to draw attention to a peculiar appearance of angulation and fixation of one border of the bowel silhouette without any appreciable distortion of the other margin which we have previously encountered in cases of diverticulosis and which we have not seen described. This wide triangular incisura was noted in 3 cases in this series, and all had had attacks of diverticulitis (Figs. 5, 6 and 7). We suspect that this roentgen finding may result from contraction of the bowel wall due to a small ciccatrix at the site of a previously inflamed diverticulum. It is probable that this type of defect may in some instances result from exceedingly deep irregular haustral contractions. The character of the defect is not unlike that seen on the greater curvature of the stomach opposite to a lesser curvature ulcer or in the duodenal cap in association with ulcer. We feel that regardless of the mechanism which may be responsible for its occurrence, its frequent association with diverticulitis is worthy of recording. Carcinoma of the colon rarely produces this appearance.

Bleeding. Too little attention has probably been given to diverticula as a cause of bleeding from the bowel in older individuals. In this entire series bleeding of some type occurred in 28 cases or 39 per cent. Melena in 3 instances was attributed to a demonstrable lesion of the stomach, duodenum or liver. In the remaining 8 cases of gross bleeding polypi were present in the rectum or sigmoid in three, leaving 5 cases or 7 per cent of the entire group without cause other than the diverticula. Occult blood was positive in the stools in 17 instances. Demonstrable gastro-duodenal lesions probably accounted for this finding in eight and hemorrhoids in one. There remains 8 cases or 11 per cent in which the diverticula may have been responsible. Ochsner and Bargen noted bleeding in 5 per cent of their cases of diverticulosis and in 22 per cent of the diverticulitis cases. There was no difference between the incidence in these two groups in our series. Bleeding occurred in 3 cases or 18 per cent in diverticulitis and in 10 cases or 18 per cent in diverticulosis. Obviously since diverticulosis is comparatively common in later life, it must constitute one of the more frequent causes of bowel bleeding in older patients.

Treatment. Bowel rest and attempt at correction of associated disturbance of normal bowel habit constitutes the principle of therapy. In the acute case without obstruction, the diet consisted of surgical liquids until all discomfort disappeared. It was then enlarged to include all foods except those with fibre, which seems to be badly borne in many instances. The addition of fiber to the diet must be made very slowly and cautiously. If bowel habit is on the "loose" side, caution is necessary in the use of very hot or cold foods and drinks. Lubricating oil by mouth and rectal instillations of olive oil or cotton seed oil are soothing, when tolerated. The medicinal management is that of the "irritable" colon, *i.e.*, sedative and antispasmodies, such as belladonna and calcium. A mixture of bismuth, barium sulphate and kaolin was used in practically every instance where inflammation was suspected without obstruction. The most important phase of therapy is the prevention of future attacks by attention to proper diet, violent exercise in some and neuroses and emotional upsets in others.

Prognosis. The prognosis of diverticulosis and uncomplicated diverticulitis is good. While many patients may have minor symptoms from time to time, major complications are rare. Twelve of our patients have been followed for 5 years or more and in no instance has a serious complication occurred. We encountered no instance of associated malignancy of the colon in this series. Ranken and Brown reported 4 cases of carcinoma in 227 cases of diverticulitis, which they believed to be entirely incidental. Ochsner and Bargen found malignancy of the colon in 6 per cent of 208 cases.

SUMMARY

A series of 72 consecutive cases of colonic diverticulosis encountered in office practice has been reviewed in order to ascertain the incidence of the abnormality and the frequency with which symptoms and complications are to be anticipated in the ambulant patient.

The study affords an interesting comparison with functional colonic disturbances in relation to age and race incidence.

Previous bowel habit of these patients has been carefully analyzed and reveals a lesser incidence of constipation than that ordinarily recorded. Diarrhea occurred in a surprisingly large number of our patients. Our statistics support the contention that diverticulosis produces symptoms from time to time in most cases. The relationship of symptoms to the number, location and size of the pouches is of interest, particularly in those with diverticulitis.

Cases with diverticulitis have been segregated and analyzed. Attention is drawn to a type of roentgen defect which may follow an attack of severe diverticulitis and which we have not seen described in the literature.

The review tends to establish the more frequent occurrence of bleeding from the bowel than is generally appreciated.

A follow-up in these office cases has indicated the rarity of severe complications and of concomitant carcinoma.

Annual Abstracts of Proctologic Literature

(May, 1934-May, 1935) By CLEMENT L. MARTIN, M.D., Chicago, Illinois

The complete bibliography from which these Abstracts were made will be published in full in the Transactions of the American Proctologic Society, 1935.

INTRAPERITONEAL VACCINATION

Steinberg and Goldblatt (see 1934 Transactions) found that the injection of heat-killed *B. coli* suspended in a saline solution and injected into the abdominal cavity, decreased the incidence of peritonitis after operation.

Hermann determined that a mixture of streptococci and *B. coli* was more effective than *B. coli* alone.

The former investigators advocate the use of a single intraperitoneal injection of 30 c.c. of 1% gum tragacanth in normal saline solution containing about 200 million heat-killed *B. coli* per cubic centimeter. (Coli-bactragen).

Following Hermann's and Steinberg's work, the use of a vaccine containing both *B. coli* and streptococci was started 8 years ago at the Mayo Clinic and a marked reduction in mortality reported from its use by Rankin and Bargen. This group continues its pre-operative use in colon cases. Some unfavorable reactions following its use have been reported. (See 1934 Transactions, Intraperitoneal Vaccination, Jones' discussion).

Potter's and Coller's experience has been favorable with Coli-bactragen (Steinberg) in 79 cases.

Gundel and Sucssbrich have treated 240 cases of peritonitis with "peritoneal serum" and have studied the cases bacteriologically. They used a polyvalent serum containing colon bacillus, gas gangrene bacillus and enterococci. They state that of 51 patients given this serum for prophylaxis or treatment, 6 died but 5 of these had heart or lung complications.

Young and Marks have used amniotic fluid concentrate in a series of 48 cases of colon resection with a mortality of only 2% in the whole group. They regard the beneficial effects of vaccines to be non-specific. A preparation of amniotic fluid is now on the market named Amfetin.

INSTRUMENTS

Bacon has devised a self-retaining illuminated proctoscope that is a short instrument tapering from the base to an expanded portion at the end, this expanded portion being grasped by the sphincter holds the instrument in place. It can also be used with a light adaptor, thus making it more generally available. He has also devised a stricturoscope consisting of a set of five tubes varying in calibre from ½" to ¼". By means of these the stricture can be calibrated, dilated, or treated before medicaments are applied. It is illuminated and has an adjustable lens which may be swung into place as desired.

DIVERTICULITIS

Various theories continue to be considered in an effort to determine the exact mode of formation of colonic diverticula. *d'Abreu* believes spasm and hyperactivity of the circular muscle of the bowel to be factors of great importance and he suggests that excessive parasympathetic action is a cause of these particularly inasmuch as relief is obtained by belladonna and hyoscyamus.

Edwards reserves surgery in diverticulitis of the colon for severe recurrent cases in which complications appear to be imminent. A right side colostomy should precede resection and should be done between attacks.

Weible suggests allowing diverticulitis of the sigmoid to go to abscess formation, then drainage being made through the anterior rectal wall by a tube extending through the anus.

Weber stresses the importance of contrast enemas after the method of Fisher and the insufflation of air following expulsion. Diagnostic efficiency is dependent upon the examiner's familiarity with the gross pathologic features of lesions as well as methods of examination.

Stewart and Illick in an article on the roentgenographic differentiation between diverticulitis and cancer of the sigmoid bring out several points of interest in a well illustrated article. They used but a pint of barium at first, examined the rectum and sigmoid thoroughly, thus avoiding confusion by other loops. The colon is then filled, and the entire procedure repeated after the patient has partially emptied the colon and again after complete defecation, often 24 hours after passing, as diverticula may be seen at this time which were not previously visible.

Lynch records a case of diverticulitis of the colon with abscess formation caused by an enema tip injury.

CONSTIPATION

Beck in "The Management of Chronic Spastic Constipation" gives a general review of the subject. Chronic constipation progresses usually through three stages: atonic, catarrhal, and spastic. The latter is perhaps the commonest variety for which the physician is consulted. He lists the causes as constitutional, eating habits, diet, cathartics, neglect, diseases, e.g. of stomach, liver, intestines, anaemia, functional neuroses, and others. Treatment is given in detail. *Spencer* does not hesitate to start his paper with "Constipation is a symptom not a disease," trite though it may be. He considers the subject from the standpoint of the physiology and the pathological physiology concerned. Associated causes may be failure to respond regularly to the urge to defecation, dietary factors, cathartic abuse, sedentary habits, obstruction from bands, and adhesions usually causing right sided stasis; stasis from emotional states, irritating food residues, lead, tobacco, caffein, organic diseases of the lumbar cord and inflamed mucosa, however caused.

In his discussion of spastic constipation he does not support the classification atonic and hypertonic (spastic). "There is little or no evidence for atonic constipation." He describes the spastic type as a definite entity and cites *Buckstein's* grouping based on stasis proximal to some particular sphincter or in a definite segment of bowel. A very rational therapy is described.

CONGENITAL ANOMALIES

Kantor describes a logical procedure to assist in locating the blind end of the rectum in imperforate anus. After a colostomy has been functioning satisfactorily, a catheter on a catheter guide is passed through the colostomy stoma into the lower segment and after incision of the anal depression a finger is passed upward to palpate the end of the catheter.

Rhodes reports a case and discusses the method of caring for this condition.

A colostomy in an infant is less satisfactory than in older patients; even so in case of complete atresia it offers the infant a better chance for its life than blind exploration to locate the rectum if the blind end is much separated from the anus.

Kantor records his study of 2000 cases of anomalies of the colon. He classifies them as follows: Redundancy, Non-rotation, Hypodescent, Hyperdescent, Hypofixation

and Hyperfixation. Unless obstruction occurs these should generally be treated conservatively. Symptomatic treatment is all that is usually required.

Gardner and Hart state that a knowledge of normal intestinal rotation is important to an understanding of the possible abnormalities. They report 2 cases of volvulus of the entire mesentery giving symptoms of duodenal obstruction and review 103 reported cases.

SECTION VIII—*Editorial*

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastro-enterological Association is in no way responsible for editorial expressions.

THE UNKNOWN LIVER

REPORTS of new procedures designed to test liver function accumulate month by month in the literature, evidence of a desire to learn more of the functions of this organ which so well hides the secrets of its behavior. And yet we must still depend primarily upon the old criteria, jaundice and enlargement, for clinical evidence of pathological changes in this organ. We do not know the cause of death after hepatectomy when adequate glucose is supplied. And the liver is now the only organ of which this can be said; in all other cases we can either provide effective substitution or adequately explain the fatal effects of removal.

One reason for the slowness with which information concerning hepatic physiology accumulates is the diversity of functions possessed by the liver; it takes an important or essential part in the metabolism of fats, carbohydrates and proteins, stores vitamins and antianemic factors, is concerned in regulating the volume and concentration of the blood, influences the mineral metabolism, and synthesizes numerous substances for excretion into the bile or in the process of detoxification.

Until recently there has been no suggestion that the liver is specifically influenced by any hormones except epinephrine and insulins. The only other regulating mechanism that has been known is the nervous system, which controls the deposition of glycogen, liberation of glucose, and caliber of the hepatic vessels. Since the demonstration by Houssay that hypophysectomy reduces the glycosuria, hyperglycemia, and ketosis of experimental diabetes, further investigation has indicated that this effect is mediated largely, at least, through the liver. Adrenalectomy has a similar effect upon the diabetic animal, but replacement therapy by anterior pituitary extracts, which restores ketosis in the hypophysectomized-depancreatized preparation, has no effect when the adrenals and pancreas have been removed (1). This suggests that the absence of the hypophysis affects the diabetic state by causing cessation of adrenal activity, and that an adrenal hormone is primarily responsible. The adrenalel cortex is known to atrophy after hypophysectomy.

But whether the effect is direct, from an hypophyseal hormone, or indirect, by way of the adrenals, it is becoming apparent that a hormone is essential for the normal activity and function of the liver. This has been suggested by Best (2) and is emphasized again by Long (3) in a recent brief review of endocrine activity and metabolism. The hepatic tissue is presumably the sole site of formation of the ketone bodies; ketosis ceases after removal of the hypophysis and can be restored by injections of anterior lobe extracts. In the liver, also, glucose is constantly being manufactured from amino acids, lactic acid, and other non-carbohydrate sources; this process of gluconeogenesis likewise fails after hypophysectomy and to its failure we can attribute, at least in part, the decrease in glycosuria and hyperglycemia of the hypophysectomized diabetic animal.

These contributions, while of the utmost value to our conception of the problems of diabetes, offer at present no ray of hope for rational therapeutic application. Even though the functions of the liver can be suppressed by removal of an essential hormone (and it has long been known that hepatic injury can produce an amelioration of the symptoms of diabetes), there appears no justification for so suppressing hepatic activity, thereby treating one metabolic disturbance by the production of another.

A "NEWS" SECTION FOR THE JOURNAL

MEN who work in similar or allied fields like to, (and *should*) know what is happening among their confreres.

Thus far, the JOURNAL has been concerned with so many problems of organization, distribution, technical questions, and the multitudinous variety of matters ever appearing when a magazine is launched, that many desirable, yet not absolutely essential, activities have had to be postponed.

Now that this publication has made for itself a place in the world's literature and the mechanics of printing and circulation well are in hand, opportunity presents itself for a "breathing spell" and the consideration of what may be pleasing, yet not strictly necessary.

A number of contributors—in this and other lands—has urged that a "News" section be provided. Such section will include items of national and international interest; happenings to physicians and scientists, in practice, at institutions for teaching and research, in medical organizations, and so on, as suitable activities occur. A "gossip column" is not intended or desired, but *real news* dealing with matters of consequence would seem worth the space given to it.

In proportion to the response from our subscribers, such "News" section will be valuable. We invite the submission of material. It must reach the Editor before the first day of any month. Brevity, accuracy and "news value" are desired.

We bespeak hearty cooperation.

Frank Smithies.

SECTION IX—*Book Reviews*

(This section is open to contributions from any medical reader, whether or not a member of the Editorial Council).

Experimental Enzyme Chemistry. Henry Tauber, Ph.D. Burgess Publishing Company, Minneapolis, Minn., 1936. 130 pages, illus. (11 x 8 in.) Fabric. Price: $3.50.

THE biochemistry of the digestive fluids and tissue juices is occupying the forefront of medical knowledge and experimental investigation. It is impossible, today, adequately to explain the so-called vital phenomena without a thorough comprehension of the chemical processes which are responsible for biologic manifestations.

Nowhere is this more true than in the field of gastro-enterology. Not only is the physiology of digestion, absorption and utilization of the various food elements dependent upon the chemistry of the digestive juices and of the cells lining the gastro-intestinal tract. The manifestations of disease also are intimately bound up with these factors which furnish a proper understanding of some of the normal as well as pathological symptoms associated with the function of the stomach and intestinal tract and its complementary glands.

It has long been known that enzymes elaborated and secreted by the cellular aggregates play a very important role in these processes. Dr. Tauber's book is a distinct contribution in this field because it summarizes the present day knowledge on the subject in a very succinct and clear manner. As a basis for diagnosis the information which can be culled from this book is of inestimable value. The bibliography is very extensive and fairly complete. As the author says in his preface, it is not possible to review all the work of recent years; but the bibliography certainly does more than that.

While this book contains considerable chemical data and many formulae, it describes many enzymes in a simple enough manner, so that even the non-technical medical man can add greatly to his knowledge of this complicated and little known subject.

In Chapter I with the Introduction, the book deals with definition of an enzyme and a discussion of the effect of temperature, hydrogen ion concentration, effect of excessive substrate, and the discussion of activators and inhibitors, and the views concerning the chemical nature of the mechanism of action. The author quotes Bechhold's analogy of the living cell as: "A city in which colloids are the houses and crystalloids are the people who transverse the streets, disappearing into, and emerging from the houses and those who are engaged in erecting or demolishing buildings. The colloids are the stable part of the organism, the crystalloids the mobile part, which, penetrating everywhere, may bring weal or woe."

It might be added that enzymes are the tools or instruments by which this is accomplished in producing changes without themselves being incorporated into these changes.

Chapter II deals with esterases derived from pancreas, stomach, liver, and certain plants, and tannase, sulphatase, and phosphatase.

Chapter III deals with proteolytic enzymes and peptidases. The structure of the enzymes is discussed, and differentiation between proteases derived from the stomach and the pancreas is made. Microphotographs of these individual enzyme crystals are clear and exceedingly well reproduced. In this chapter the subject of crystallization is given in detail. Plant proteases are also discussed in this chapter.

Chapter IV deals with amidases which act upon amino acids, and acid amids. In this chapter urease is discussed at considerable length.

Chapter V deals with carbohydrases, the carbohydrate splitting ferments which have probably been studied more extensively than any other type of enzyme. This chapter not only discusses the various saccharases, but also discusses the glucosidases and emulsin, and those enzymes which split starch and glycogen. The identification of molecular structure by means of enzymes receives attention in this book, and the reader is referred, for the considerable amount of information which could not possibly be included in this small book, to the extensive bibliography which follows each chapter.

Chapter VI deals with catalases.

Chapter VII deals with oxidizing enzymes which are subdivided into the anaerobic group and the aerobic group. A subject of considerable importance, particularly in the true oxidase group, is a discussion of the Vitamin C oxidase of ascorbic acid. The ferment which oxidases ascorbic acid is of tremendous importance in the light of the role which this Vitamin plays in the cure and prevention of disease and its relationship to the chemical processes associated with maintenance of normal physiology.

Chapter VIII deals with the oxidation system associated with coenzymes, and which belong in the group of dyes such as flavine, as well as other colored enzymes.

Chapter IX deals with the carbonic anhydrase which is associated with the liberation of carbon dioxide into the capillaries of the lung.

Chapters X and XI discuss the enzyme chemistry of alcoholic fermentation and bioluminescence.

This book therefore is of value, not only to students of nutrition, but also to physicians who seek satisfactory explanation for many of the symptoms which they observe in connection with gastro-intestinal and nutritional disturbances.

Benjamin Jablons, New York City.

The Patient and the Weather. Volume 1, Part 2. William F. Peterson. Edwards & Co., Publishers, Ann Arbor, Mich., 1936.

THIS big volume of nearly 800 pages rather overwhelms one—it represents such an enormous amount of work and it covers such an enormous field. One marvels at Dr. Peterson's industry and his devotion to his subject and his knowledge of the literature.

He is convinced that changes in weather can account for almost any change that ever takes place in the health or in the bodily functions of a man. The book is filled with complex graphs showing the relations between temperature curves, barograms, storms, etc., and changes in bodily chemistry or pulse rate or blood pressure or what not.

The average physician is prepared to receive the information that arthritic joints become more painful as storms approach but he will probably be a bit surprised when told that his patient died on a certain day after operation because an anticyclone or something came along. He will want to have more proof of this and if he does not find it, he is likely to lose faith in the author. As we have said in reviewing previous volumes issued, it would be most regrettable if after all this tremenous labor by Doctor Peterson and his colaborators, the medical world should "walk by" as the reviewer has had to do, and say, "We marvel at the man's industry; we hope he has proved his thesis; we wish we could spend weeks and months in examining the graphs so that we could tell whether or not the facts justify the conclusions, but after reading here and there for a few days and running into many things that look to us more like chance and coincidences than proofs, we hesitate to spend more time on the book—we'll let someone else make an analysis and a more readable abstract of it."

This would be most regretable. Unfortunately, it is extremely difficult for the human mind to judge of complicated graphs such as are published in this book. It is too hard to remember after studying twenty curves how many times the lines ran parallel and how many times they ran higgledy-piggledy, or one line went up while the other went down. The visual method is too precarious and too widely open to self-deception. Our impression is that the statistician's method of correlation is the only one that will ever bring order out of chaos in these books and will show in a minute what degree of relationship there actually was between two sets of data. When there is a perfect relationship, either positive or inverse, between, let us say, barometric pressure and blood pressure, the index will be either plus 1 or minus 1, and when there is no agreement the index will approximate 0.

If Doctor Peterson wants his enormous labors to influence medical practice and if he wishes his books to be read and his theses accepted, it would seem as if he ought to get a statistician to calculate the indices of correlation for the data now published in the form of curves. Then the men who are competent to pass on Peterson's work and to appraise it can pick out in a few moments the experiments that showed a correlation between weather and bodily functions. Even then, however, much room will be left for judgment as to whether or not an experiment was run long enough to prove anything. If an experiment is so short as to cover only one episode, as many of Peterson's are, it may be suggestive, but that is all. What is the use of showing that an epileptic attack coincided with an anti-cyclonic storm? For that matter, even the method of correlation has its dangers. Thus one might find that the curve representing increased use of electric refrigerators in the United States parallels beautifully the curve representing the national debt of Japan, and yet one couldn't say that one was cause and the other effect.

All of which does not keep us from recommending this book to all of those who like to think. It is crammed with information and suggestion, and for a medical book, it is unusually well written. The main criticism is that it confuses through its very richness. It would have been more convincing if it had had fewer illustrating protocols and more careful analyses and explanations of the ones presented. Peterson would have helped his cause much by leaving out protocols of the many inconclusive experiments, some so inconclusive as to throw doubt on the good judgment of a man who would show them at all.

Walter A. Alvarez, Rochester, Minn.

SECTION XII—"*The Clinic*"

Intestinal Polyposis: Adenomatosis Coli and Polyposis Cystica Intestini*

By

JOSEPH FELSEN, M.D.
NEW YORK, NEW YORK

THE term "intestinal polyposis" has sometimes been used indiscriminately to describe two separate and distinct clinical and pathological entities, namely, *adenomatosis coli and polyposis cystica intestini*. The purpose of this communication is to differentiate these two conditions.

1. *Etiology.* There are two main theories as to the etiology of adenomatosis coli, both of which have much to support them. Ribbert (1) suggests their origin in embryonal rests, a theory intimately connected with oncogenesis in general. Versé (2), Ewing, Lockhart-Mummery, Dukes (3) and others propose an inflammatory basis for the development of these multiple tumors without excluding some *anlage* peculiar to the individual or family. The consensus of opinion appears to be that the condition has a definite hereditary tendency of the Mendelian type. Every specimen in our series falls in this group, two or more members of the

*From the Department of Laboratories and Research, The Bronx Hospital, New York, N. Y.
Submitted September 11, 1936.

family having had the condition, three generations having been involved in one instance. Polyposis cystica intestini, however, involves no hereditary factor. Evidence has recently been presented indicating that the disease is acquired and is the late result of bacillary dysentery (4). The similarity lies only in the familial incidence which is wholly explainable in polyposis cystica on the basis of contact infection during the early stage of acute bacillary dysentery. In follow-up studies of more than 200 cases of acute bacillary dysentery not one instance of adenomatosis coli has been encountered. This suggests that if a chronic inflammatory process precedes the neoplastic one, it is probably not due to bacillary dysentery.

2. *Pathology.* Adenomatosis coli is characterized by the development of multiple solid adenomata of the mucosa of the colon. We have never seen these tumors extend beyond the ileocecal valve although involvement of the small bowel has been described by Lubarsch

TABLE I

Differential features of intestinal polyposis

Polyposis Cystica Intestini	*Adenomatosis Coli*
1. Inflammatory.	1. Neoplastic.
2. Acquired.	2. Hereditary factor.
3. The late result of bacillary dysentery.	3. Etiology unknown.
4. Mucosal ulceration, mural fibrosis and stenosis involving entire segment of bowel.	4. No mucosal ulceration or mural fibrosis. Stenosis, if present, is local and due to size of tumor or desmoplasia associated with malignancy.
5. Does not become malignant.	5. Multicentric malignancy frequent.
6. Process often extends beyond ileocecal valve into ileum or may involve any part of the small or large bowel in segmental fashion.	6. Generally limited to colon.
7. Loss of haustration.	7. No loss of haustration.
8. Ideal therapy is the prevention of bacillary dysentery.	8. Ideal therapy is complete resection.

(5), Niemack (6), Ribbert (7), Petrow (8) and Hauser (9). Other types of tumors, however, may occur concomitantly in the small bowel, such as leiomyoma or lipoma. Gatersleben (10) reports a case of multiple polyposis of the small intestine with malignant degeneration in a woman of 22 and states that this is the fourth case of polyposis in this location to be reported in the literature. Adenomatosis coli represents a neoplastic process, the tumors beginning as small, punctate, flattened elevations of the mucous membrane scarcely visible to the naked eye. Slowly increasing in size these areas become larger and more rounded. The surface appears smooth and reddened, but close inspection of the larger tumors generally reveals a division into closely-knit cauliflower-like lobules. The typical fully developed adenoma is mushroomed at the tip of some redundant mucosa, eventually becoming more and more pedunculated because of traction on a loosely attached mucous membrane and underlying submucosa. Sometimes these pedicles, which consist of mucosa and underlying vascularized connective tissue, become quite long, a tumor located in the sigmoid not infrequently appearing at the anus. The process probably is the result of an attempt by the bowel to expel the tumor as it would a foreign body. The pedunculated tumors are generally benign. When malignancy supervenes the tumor which originally had a short pedicle becomes sessile, spreads laterally, undergoes central necrosis and eventually takes on the appearance of adenoma malignum or adenoma destruens. It seems quite certain that they remain local for a relatively long time, are only slowly invasive and, when resected at a reasonably early period, do not recur. Most of the cures of carcinoma of the colon probably fall in this group. These tumors, whether adenomatous or malignant, are well vascularized and are prone to repeated hemorrhage. The blood vessels are located in the connective tissue core which is generally continuous with the submucosa of the bowel. The pedicles, which consist of mucosa and submucosa, may undergo torsion with subsequent partial or complete necrosis of the adenoma. Inasmuch as adenomatosis coli is a condition in which the adenomata are scattered all over the colon, malignancy may occur simultaneously in several tumors—a true example of multicentric malignancy (11). This can be readily shown in the case of two such tumors by means of serial sections of the intervening intestine. There is no undermining of the mucosa by spread of cancer cells along the submucosal lymphatic plexus and reappearance at another point of the intestine. Each nidus is separate and distinct. We have never seen adenoma malignum or adenoma destruens in the small bowel associated with adenomatosis coli, a condition which should be encountered if adenomatous polyps occurred with any appreciable frequency in the small intestine. The rarity of primary carcinoma in the latter is well known. Aside from the tendency to multicentric malignancy in adenomatosis coli the condition seems to be associated with some underlying pathological *anlage* or tendency to the development of other intestinal pathology. Indeed, this is the rule in nearly all neoplastic diseases of the colon. Thus, villous tumors, submucosal lipomata or diverticula are often associated lesions. Another differential point is the absence of ulceration between the polyps, the intervening mucosa generally being quite normal. Whether adenomatous polyps are the precursors of all carcinomata of the bowel, as suggested by Schmieden and Westhues, Fitzgibbon, Rankin and others is perhaps still somewhat debatable. However, this view has been misinterpreted by many to mean that all adenomatous polyps become malignant. This, of course, is not so. The same mistaken point of view existed not so many years ago with regard to ulcers of the stomach becoming carcinomatous. The incidence of multiple, silent, benign, adenomatous polyps in our necropsy series is 3.03% in 462 successive necropsies (4.1% excluding 119 babies). The figure increases in direct proportion to the care with which the intestine is examined in the autopsy room. The earliest histopathologic changes suggesting malignancy appear to be loss of ducts, imbalance of stroma and glands, atypical glandular morphology, multiplication of cell layers, nuclear hyperchromatism and penetration of the muscularis mucosae. Even after this occurs it should be remembered that the submucosal lymphatic plexus often acts as an effective barrier to the further spread of the disease for many months, perhaps as long as a year. The prognosis in this type of tumor, generally grade one, is

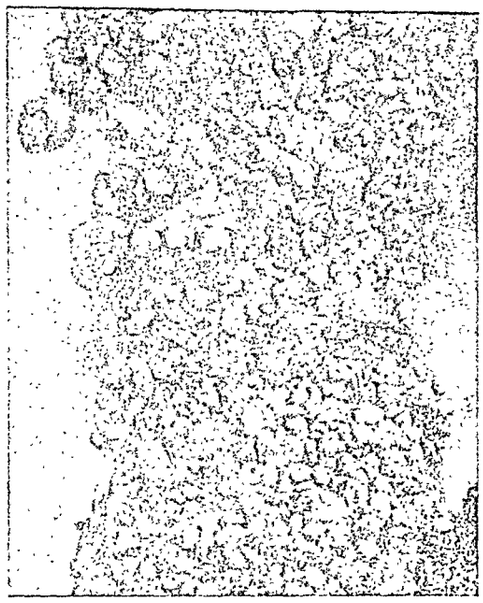

Fig. 1. No. 578. Adenomatosis coli in a male, age 45, in whom the chief symptoms were diarrhea and hemorrhage. Note both the sessile and pedunculated tumors in all stages of development with scarcely any normal mucosa visible.

therefore correspondingly good. Adenomatosis coli has never been observed in the newborn.

Polyposis cystica intestini has only the remotest resemblance in the gross to adenomatosis coli. The polyps on close scrutiny through the sigmoidoscope are seen to be pinched off bits of swollen mucous membrane with intervening areas of ulceration. The condition is inflammatory, not neoplastic and represents one phase in the development of the disease known as chronic ulcerative colitis. Contiguous intramural infection is always present and may be associated with intramural abscess formation, fibrosis or both. Often the solitary acuminate lymph nodules are totally destroyed and the colon becomes essentially a narrowed, thickened, infected, vascularized tube of connective tissue. Extensive linear, serpiginous and geographic areas of ulceration alternate with small or large areas of intact mucosa which, because of blockage of ducts by scar tissue and retained gland secretion, take on a polypoid appearance. They can hardly be regarded, however, as true polypi and in this sense the term is a misnomer. The colon may be involved in a segmental fashion and the process often extends into the appendix and beyond the ileocecal valve into the small intestine, particularly the distal portion of the ileum (chronic distal ileitis). Loss of haustration is always seen in the roentgenographic examination and diffuse stenosis of the bowel lumen is frequent. Bleeding in this condition occurs chiefly from the ulcerated areas, the infection eventually causing necrosis of the superficial vessels. Epidemiological, clinical, pathological, bacteriological and serological evidence point to polyposis cystica intestini as being the late result of bacillary dysentery. The original organism dies out and secondary non-specific infection occurs through the ulcers originally produced by B. dysenteriae. We have never seen malignancy directly attributable to or even remotely associated with this condition, although it has occasionally been described. Every case of polyposis in which we have seen this occur has been one of adenomatosis coli ante-

Fig. 2. No. 6443. Adenomatosis coli in a female, age 21. Arrow points to an associated villous tumor. Maternal uncle and maternal grandmother died of the same disease.

Fig. 3. No. 2604. Multicentric malignancy in descending colon and sigmoid in a male, age 38. Five years after resection there was no evidence of recurrence or metastasis. Other adenomata were present, but not removed. Upper tumor is a benign adenoma; middle and lower tumors are malignant.

Fig. 4. No. 7160. Chronic ulcerative colitis associated with polyposis cystica intestini. Entire mucosa is ulcerated except for the small scattered islands visible in the photograph. Original infection due to B. dysenteriae Flexner.

dating and existing independent of an original infection with B. dysenteriae. Multicentric malignancy has never been noted in polyposis cystica intestini.

3. *Diagnosis.* The clinical diagnosis of adenomatosis coli is generally made by direct visualization of the tumors through the sigmoidoscope. One of the tumors may be snared off for microscopic study which shows the characteristic adenomatous structure. Roentgenographic examination reveals multiple smooth circular defects which projects into the column of barium. The diagnosis of polyposis cystica rests on the characteristic polypoid islands of mucosa with intervening areas of ulceration readily seen through the sigmoidoscope. During acute exacerbations a mucopurulent exudate may be seen and free bleeding is common. The bowel is stenosed due to extensive intramural fibrosis and roentgenographic study reveals a typical loss of haustration, mural thickening and defects in the mucosal pattern corresponding to the ulcerated areas lying between the polyps. Biopsy of these polyps shows only chronic inflammation, but *no evidence of neoplasia.* Even at this late stage one may occasionally recover B. dysenteriae if the organism is sought for persistently. Agglutination titer against B. dysenteriae usually positive if a sufficient number of strains are used in the tests.

4. *Symptomatology.* In adenomatosis coli, diarrhea, bloody intestinal discharges, cramps, anemia and loss of weight are common symptoms. In polyposis cystica intestini similar symptoms occur, but a careful history and epidemiological study often will reveal that the process is merely a perpetuation of an original acute bacillary dysentery. The intestinal discharges are not only bloody, but often purulent, indicating the inflammatory nature of the disease. Intramural abscess formation is common and is accompanied by a septic type of temperature which promptly subsides following evacuation of the abscesses. The natural course of the disease is one of periods of remission and exacerbation which appear to correspond to relatively high and low degrees of immunity to the primary and secondary infecting organisms.

5. *Therapy.* The treatment of adenomatosis coli is surgical—either a short circuiting operation to divert the fecal stream or complete colectomy. The latter operative procedure is attended with a high rate of mortality and should be undertaken only by experienced surgeons. Repeated blood transfusions before and after operation are helpful. Fulguration has been used successfully on adenomata in portions of the bowel which could not be resected. The ideal treatment of polyposis cystica intestini (chronic ulcerative colitis) is the prevention of bacillary dysentery. Once fully established, polyposis cystica intestini is extremely resistant to therapy. Every patient with acute bacillary dysentery who does not recover within three weeks should receive active immunization with D-C vaccine (Dysentery-Colitis vaccine containing polyvalent autogenous and stock strains of the original infecting dysentery organism, enterococcus, hemolytic and non-hemolytic B. coli). This procedure should be supplemented by D-C antivirus, intestinal oxygenation and repeated transfusions in which suitable individuals who have recovered from bacillary dysentery are used as donors. Immunization should be carried out intensively *before* the chronic lesions have been well established. Surgery has a very limited place in polyposis cystica intestini. Resections are attended with a relatively high rate of mortality and recurrences are frequent. The latter are due to cutting through infected bowel or overlooking "skip areas" of ulcerative colitis. Short circuiting operations do not clear up the infection and the use of a stoma for irrigation purposes is of very doubtful value.

SUMMARY

Adenomatosis coli and polyposis cystica intestini are two entirely different conditions. Epidemiological, clinical, pathological, serological and bacteriological studies indicate that polyposis cystica intestini is the chronic stage of acute bacillary dysentery. Adenomatosis coli, on the other hand, is a neoplastic disease prone to multicentric malignancy and unrelated to bacillary dysentery.

Diffuse Polyposis of the Colon*

A Case Report

By

L. K. FERGUSON, M.D.†

PHILADELPHIA, PENNSYLVANIA

VIRCHOW (4), in 1863, first described the form of diffuse polyposis of the colon, and later Cripps (1), in 1882, pointed out the familial tendency in this disease. Since that time many authors have reported isolated cases. Rankin (3) recently reported 11 cases which he treated by total colectomy, with 2 deaths. Janssen (2), in 1932, reported 2 cases of this disease in brothers, with the history that there was probably the same disease in the father. In an investigation of the family he also found 2 other cases.

The patient to be reported illustrates the characteristic symptoms of this disease. She was a young woman 37 years of age whose mother had died at the age of 45 with what was believed to be carcinoma of the rectum. She was markedly thin and emaciated, weighing about 90 pounds; the hemoglobin was 56%. She gave a history that for 9 years she had had attacks of diarrhea, lasting from 3 weeks to 2 months; between the attacks there were often periods of rather marked constipation. During the year before admission, the attacks were almost constant. The movements were liquid and as many as 8 to 10 a day and contained much mucus and often blood. On proctoscopic examination in November, 1935, the bowel wall was found to be literally covered with palpable and visible polyps. A barium enema showed a diffuse polyposis involving the entire large gut. (Fig. 1).

On admission to the hospital she was prepared for operation by several blood transfusions, and on December 14th, the abdomen was opened through a grid-iron incision on the right side. The ileum was sectioned, the distal end inverted, and a mushroom catheter was sewed into the proximal end and brought out through a muscle-splitting incision in the right rectus. At the time of operation a mass was palpable in the sigmoid; this was believed to be a carcinomatous degeneration of the polyps.

The patient did fairly well. Her fluid intake was augmented to about 3000 c.c. a day by the use of intravenous infusions and blood transfusions. The wounds healed by primary intention and the patient was up and about the ward for a time, but she became a psychological problem, refusing to eat solid food. At her own request, she was permitted to go home but her nourishment and care were not of the best and she steadily became weaker. She was readmitted to the hospital. Fluids were supplied in abundance intravenously and, in addition, four transfusions were

Fig. 1. Barium enema, showing diffuse polyposis throughout the entire large gut.

*Read before the Philadelphia Academy of Surgery, March 2, 1936.

†Associate in Surgery, University of Pennsylvania.

Submitted September 6, 1935.

given, but she never could be made to eat solid foods and finally died 45 days after operation.

This case is of interest in pointing out several difficulties which may arise in the care of such patients. In the first place, the preparation of the patient for operation must be a very thorough one. The patients are usually anemic and markedly dehydrated; fluids and blood must be supplied before operation may be performed.

Secondly, the postoperative care of patients with ileostomy cannot be treated lightly. The loss of fluids following operation is often considerable and it is important that an accurate estimate of fluid loss be kept in order to gauge the fluid intake.

Thirdly, as soon as possible, these patients should be permitted to eat solid food, in order to hasten the development of a colon-like hypertrophy of the terminal ileum, which in a measure reduces the fluid loss.

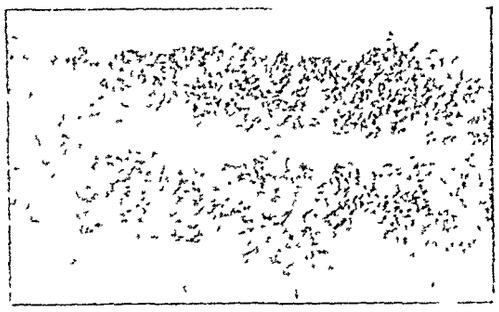

Fig. 2. Diffuse polypoidosis of large intestine with foci of adenocarcinomatous degeneration in the sigmoid. The upper section is the ascending colon, and the lower section is the sigmoid. Malignant degeneration was found in four areas (see arrows), from which sections were made.

Fourthly, the operation of choice in these cases is a resection of the colon or colon and rectum because of the almost certain danger of carcinomatous degeneration of the polyps. In this patient a carcinomatous degeneration had taken place in three of the masses. (Figs. 2 and 3).

Fifthly, Rankin's experience in handling these cases should be noted. Following a preliminary ileostomy, he permits the patient to regain strength and normal bowel function for a period of 3 to 4 months and then performs a colectomy in stages down to the sigmoid. He points out that in resection of the transverse colon, his best results have been obtained by dividing the posterior leaf of the transverse mesocolon so as to leave the greater omentum. In his later cases, he has attempted to leave the rectum and lower sigmoid, to remove the polyps in this area by effulguration. If he is successful in the latter procedure, he then forms an anastomosis between the ileum and the remaining sigmoid so as to again reform the continuity of the intestinal tract and to permit bowel movements per rectum.

SUMMARY

This patient presents the typical history, diarrhea in the young anemic patient, which is seen in diffuse polyposis. The disease is probably familial in this case, and had progressed to a carcinomatous degeneration of three of the polypoid masses. The problems arising in the treatment of such patients have been discussed.

DISCUSSION

DR. CALVIN M. SMYTH, Jr. It is very important to place cases of this type on record since no one individual sees a sufficient number to enable him to speak with much authority and it is only by referring to collective experience that anything can be learned regarding the proper method of procedure. Some years ago in a similar case we performed a terminal ileostomy and the patient improved rapidly. Without previous experience to guide us we resected his colon at the end of three weeks and the patient died. At the present time we have a young woman of 28 years who was admitted originally to the Medical Service with a grave progressive anemia, diarrhea, bleeding from the bowel and loss of weight. A diagnosis of diffuse polyposis was made by X-ray and sigmoidoscopy. After repeated transfusions we performed terminal ileostomy and her improvement has been truly remarkable. The terminal ileum is gradually taking over function of the large intestine and she is eating solid food and rapidly gaining strength. Naturally she is anxious to have the rest of her surgery done but with our previous experience and with the experience of others in mind, she is being sent home to wait for two or three months. Many surgeons fail to realize that ileostomy is a formidable procedure. For one thing the disturbance in water balance following it is sufficient to cause death and it is not only a question of replacing fluid but of keeping a close check on the electrolyte balance and gauging the administration of water, salt and sugar accordingly. One of the most important points brought out in Doctor Ferguson's paper is the necessity of a long period of waiting between the performance of ileostomy and colectomy. The latter should never be undertaken until one is perfectly sure that the maximum improvement has been obtained.

ABSTRACTS

CLINICAL MEDICINE

MYERSON, A., AND RETVO, M.

Benzedrine Surfate and Its Value in Spasm of the Gastro-intestinal Tract. J. A. M. A., Vol. 107, pp. 24-26, July 4, 1936.

The muscular activity of the gastro-intestinal tract, normal and abnormal, has interested physiologists, roentgenologists and clinicians because of its close relationship to the emotional state of the patient. Spasm of the gastro-intestinal tract arises from many causes. It may result from (1) functional disturbances, such as worry; (2) the neuroses and psychoses; (3) intrinsic disease of the gastro-intestinal tract, as a cancer, an ulcer or appendicitis; (4) extra-alimentary conditions such as renal colic, plumbism or tabes dorsalis.

Many drugs have been tried to abolish these spastic manifestations, among them atropine and benzyl benzoate, but results have been poor. In order that a drug be valuable it must fulfill the following requirements: (1) the effect should not be prolonged; (2) it should not cause unpleasant or dangerous reactions; (3) it should be rapidly and uniformly effective when given orally, as some patients may object to injection methods; (4) the routine roentgen studies should not be interfered with; (5) it should be generally available and inexpensive.

Benzedrine in the form of the sulfate has been tried and has been found to lessen or abolish spasm of the gastro-intestinal tract within a few minutes after its oral administration. It is said to act on the sympathetic system and therefore is a sympathicamimetic drug. The spasm is relieved when due to unpleasant emotion, organic disease of the tract, or reflex spasm from organic disease elsewhere in the body. This facilitates roentgenographic differentiation between functional and organic spasm, and gives better visualization of organic lesions. The drug has also been used clinically in the relief of spastic colitis and pylorospasm.

SANDWEISS, DAVID J.

Treatment of Gastro-duodenal Ulcer with Histidine Monohydrochloride. J. A. M. A., Vol. 106, pp. 1452-1459, April 25, 1936.

The treatment of peptic ulcer by the Sippy method, by modifications of it, or by surgical intervention is unsatisfactory in many cases. There are many cases which respond at first, but then relapse. Whether this response to treatment is merely coincident with a natural remission in the course of the ulcer, or whether it is actually a response to treatment is not known.

Many new methods of treatment have recently been advocated. Among these is the injection of histidine intramuscularly. The La Rostidin brand of histamine (histidine monohydrochloride) is the most widely advocated product for this.

The rationale of this treatment, according to Weiss and Aron following their work on dogs, is that ulcers develop because of a deficiency of the amino acid histamine. Their experimental work does not prove this conclusively; in fact, similar work by other workers points in a different direction.

Sandweiss, working on sixty-seven patients with peptic ulcer, of which fifty-three were treated with the diet-alkali regimen, and forty with histidine, had the following results:

1. Of the patients treated with diet-alkali, 51 per cent became symptom free and 20.7 per cent were moderately improved. Of the patients treated with histidine, 55 per cent became symptom free and 20 per cent were moderately improved.

2. Of seventeen patients treated with histidine after failure to respond to the diet-alkali management, 52.9 per cent became symptom free and 17.6 per cent were moderately improved.

3. Of nine patients treated with the diet-alkali after histidine failed, 42.8 per cent became symptom free and 28.6 per cent were moderately improved.

4. By changing from one treatment to another, 73.5 per cent became symptom free and 13.4 per cent were moderately improved. Of the nine patients not responding to medical treatment, four required surgical intervention and five had medical complications, such as myocarditis, hyperthyroidism or arteriosclerosis.

5. Eighty-five per cent of the patients treated with histidine had remissions after six months, and 31 per cent of those on the diet-alkali regimen had remissions after six months.

6. Twenty-four consecutive daily injections of histidine are not essential to produce a remission or prolong a symptom-free period. If eight injections at the most do not produce a disappearance of all symptoms, further injections will not be of great value.

7. About one-third of seventeen patients showed a slight increase in the acid curve; one-third showed a slight decrease; and one-third showed no change.

8. Twenty-four patients who were checked either by X-ray or operation after histidine treatment did not show any disappearnace of the ulcer deformity.

9. Sixteen of the patients treated with histidine developed mild reactions.

The conclusion was reached that, because of results paralleling those obtained in the diet-alkali treatment, histidine was of value only as an accessory in the treatment of those cases which do not respond well to the diet-alkali method.

MOUNT, G., MOUNT, F. R., *and* HUNTER, W. C.

Calcification in the Spleen. J. A. M. A., Vol. 107, pp. 203-205, July 17, 1936.

Calcification in the spleen usually occurs in small zones, in the capsule, in small infarcts, and in tuberculous or gummatous masses. It also occurs in thrombosis of the splenic vein, echinococcus cyst, and in diseases associated with extensive general calcification.

The following is the history of a woman, aged 44, who over a period of two years complained of an uncomfortable feeling of pressure in the left hypochondrium, which during the last six months was aggravated by eating, stooping forward and lifting of the left arm. Three months previous to the onset of these symptoms she was in an automobile accident in which she injured her left side just below the ribs.

Physical examination revealed a mass in the left hypochondrium which was apparently the spleen. This was confirmed by the fluoroscope. Splenectomy was done and the patient made a satisfactory recovery.

Examination of the spleen revealed a large calcified mass in the hilus, which mass extended into the substance of the spleen leaving only a small area of normal spleen at the upper pale. Microscopic examination revealed large calcified areas surrounded by areas of hyaline degeneration. The etiology of this condition was thought to be trauma, at the time of the automobile accident, with rupture of the splenic pulp without tearing of the capsule, followed by organization of the hemotoma which formed with the later deposition of calcium salts.

Francis D. Murphy, Milwaukee.

EXPERIMENTAL PHYSIOLOGY

FITZ-HUGH, THOMAS, JR.

Experiments with "Depepsinized" Human Gastric Juice in the Treatment of Pernicious Anemia. Am. Jour. Med. Sciences, p. 168, August, 1936.

After discussion of work done by Roger Morris and his associates, Minot and Castle, Wilkinson and Vlados, Fonts and Zerfas and Greenspon, the authors report their studies in three cases of pernicious anemia, in relapse, with red cell counts between 1.4 and 2.3 million and hemoglobin from 40 to 58% (Sahli). The diet was iron-free. Gastric juice concentrates for parenteral administration. "Depepsinization" was carried out by the method of Fenger and Andrews as recommended by Greenspon. Normal gastric juice was obtained from ward and clinic patients with normal blood counts, normal gastric acidity and without evidence of tuberculosis, syphilis or other active infection. The first patient, a woman, was given an injection of 11 c.c. of a concentrate representing 200 c.c. of fasting "depepsinized" gastric juice from her own stomach during the preceding week. Reticulocyte fluctuation, for 10 days before and 6 days thereafter, varied between 0.2% and 1.3%. This was considered a completely negative result. This experiment was undertaken with the thought that if Morris' so-called addisin produced merely non-specific irritation effects rather than true "hormonal stimulation there would be no apriori reason why pernicious anemia juice might not be as effective as normal juice.

A second experiment on this same patient consisted of introducing into her stomach 500 c.c. of pooled normal "peptically inactivated" fasting gastric juice through the stomach tube. Then food was withheld for 5 hours and before it was taken, gastric lavage was repeated. 3 days later another 500 c.c. of normal gastric juice was given by tube. The reticulocyte count showed a slight increase to 4% on the 3rd day after the first gastric juice feeding; i.e., on the day of the second feeding. One day later reticulocytes were 5% and then fell in 6 days to 1% and the red cell count and hemoglobin were slightly lower than before any experiments were begun. This patient later showed the usual hematologic recovery on a parenteral potent liver extract. The observation was not considered as proof of anything.

Experiment 3 was on a man and lyophilized P.A. gastric juice was used as a concentrate intramuscularly. This was followed by a local and systemic reaction. Reticulocytes rose from 2.1% before the experiment, to 4.7% on the 12th day after the injection but the red cells and hemoglobin declined.

Experiment 4 consisted of giving this same patient 11 c.c. concentrate of the acetone soluble fraction of lyophilized normal fasting gastric juice. This was followed by a reticulocyte rise from 1.4% to 3.5%; the red cells and hemoglobin remaining unchanged.

Experiment 5 consisted of giving intramuscularly 12 c.c. concentrate of 700 c.c. of normal "depepsinized" human gastric juice. No favorable effect was observed.

Experiment 6 consisted of parenteral injection of a concentrate of the patient's (pernicious anemia in relapse) own gastric juice. In 4 and 8 days respectively, reticulocytosis of 4.5% and 5.3% were observed but otherwise there was no change in the blood picture.

Experiment 7, the same patient, received a concentrate of normal depepsinized gastric juice without effect. In Summary, all the procedures with depepsinized gastric juice failed to excite a significant reticulocyte response in the cases of pernicious anemia the authors studied.

Allen Jones, Buffalo.

ROENTGENOLOGY

MERRITT, E. A., AND RATHBONE, R. R.

The Diagnosis and Roentgen Treatment of Carcinoma of the Head of the Pancreas. Radiology, Vol. 26, No. 4, April, 1936.

Merritt and Rathbone state that of all the neoplasms which are observed to occur in the pancreas, carcinoma is by far the most frequent. Sites of predilection are the head, the body, and the tail of the organ respectively. . Hoffman, in 1934, set the mortality from cancer of the pancreas at not less than 3 per cent of the total mortality from all forms of malignant diseases in the United States.

The cause and nature of carcinoma of the pancreas is presented briefly. The symptomatology and pathology of carcinoma of the pancreas are discussed and the surgical treatment.

The authors present the history of a white woman, aged 47 years, with a history of epigastric disturbances during the previous two years, followed by a recent appearance of painless jaundice, with clay-colored stools and vomiting. At operation the gall bladder was enlarged and tense, but no stones were found. The head of the pancreas was very hard and nodular; the tail of the pancreas was soft. The liver was enlarged; no metastases were noted.

Roentgen therapy was advised. In the first series, extending from August 30 to September 18, 1933, the patient received a total dosage of 4,500 r (2,250 r to the anterior and 2,250 r to the posterior pancreas). The tumor dose was 1,800 r. The following factors were used: 220 kvp., 20 ma., 50 cm., distance; Thoraeus tin filter equivalent to 2.0 mm. copper, 250 r (measured in air) to alternate 15 x 15 cm. anterior area and 20 x 20 cm. posterior area. The authors report that the patient's general condition improved during treatment and the vomiting stopped.

In July, 1935, the patient ran a septic temperature and became very toxic and died August 3, 1935. The autopsy revealed a terminal pneumonia, multiple metastases of both lungs, abscess of liver, hepatitis, chronic cholecystitis and cholelithiasis. There was no malignancy of the pancreas; it showed a chronic interstitial pancreatitis.

In the summary, the authors state that clinically the patient presented evidence of carcinoma of the pancreas and this was verified by surgical exploration. A cholecysto-jejunostomy was done to relieve the biliary obstruction. The patient was given intensive postoperative roentgen therapy with complete disappearance of the tumor and apparent clinical recovery for a period of one year when she developed signs and symptoms of liver metastases. No evidence of malignancy was found at autopsy. The authors present this case to stimulate further trial of roentgen therapy in carcinoma of the pancreas.

ABDOMINAL SURGERY

BLAHD, M. E.

Surgical Indications for Peptic Ulcer and Its Surgical Management. S. G. O., Vol. 62, No. 2, pp. 203-212, Feb. 1, 1936.

In addition to obstruction, perforation and severe uncontrollable hemorrhage, the author proposes a fourth positive indication for surgery in the treatment of peptic ulcer. He concurs with Boas of Berlin in the belief that the character of the ulcer and not the number of medical cures should be the factor to determine the need for surgical treatment. He feels that the penetrating type of ulcer is rarely if ever cured under a medical regimen and that when it is demonstrated roentgenographically as a fleck in a crater it constitutes the fourth positive indication for surgery.

Subtotal gastrectomy is proposed as the operation of choice, securing upward of 90 per cent of permanent cures.

Statistics of the primary mortality following gastric resection show that it is higher than that of gastro-enterostomy, but when the secondary mortality following the latter procedure is taken into consideration there is very little difference. The secondary mortality following gastric resection is practically nil.

Pre-operatively a medical regimen designed to build up the patient is followed for a period of time. Gastric lavage is recommended. Some form of regional anesthesia is preferred. A detailed description of a posterior Polya type of gastrojejunal anastomosis as

modified by Finsterer is given in detail. The stomach is sectioned at right angles to the body axis so as to favor rapid emptying and prevent regurgitation from the afferent jejunal loop.

Postoperatively nothing is given by mouth during the first five days; venoclysis of 3,000 cubic centimeters of 2.5 per cent glucose in normal saline is given daily. If gastric distention occurs, drainage is instituted by a Levine tube. The diet is enlarged until at the end of three weeks the patient leaves the hospital with no restrictions whatever upon his food.

Eleven figures and a bibliography accompany the article.

Nelson M. Percy, Chicago.

MENTZER, STANLEY H.

Obstructive Cholecystitis — With Particular Reference to Acute Obstructive Cholecystitis and Its Sequelae. S. G. O., 60:879-887, May, 1936.

The term "acute obstructive cholecystitis" is suggested for the suddenly obstructed and acutely inflamed gall bladder which is still filled with bile. "Hydrops" and "empyema" are used to designate the obstructed gall bladders filled with mucus or pus. While these two conditions result from prolonged obstruction, they are subject to acute and subacute exacerbations. Acute cholecystitis may occur at times without obstruction. The indicated treatment depends to a large extent upon the differentiation between the obstructive and non-obstructive lesions and to a lesser extent upon the differentiation of the various types of acute obstruction. The history of biliary distress, the presence of a tender mass, the height of the fever curve, and the degree and character of the leucocytosis should aid in making a satisfactory differentiation. Often, however, this seems quite difficult and if the fever, tenderness, rigidity, and leucocytosis persist under observation of 6 to 48 hours, the case should be considered as an advanced, acutely inflamed and obstructed gall bladder requiring immediate surgical attention. Jaundice is not an important symptom. Waiting for a subsidence of the acute infection is a dangerous form of conservatism accompanied by an increased incidence of perforation and an increased mortality. The operation of choice from the standpoint of immediate mortality as well as subsequent morbidity is cholecystectomy rather than cholecystostomy.

J. Duffy Hancock, Louisville.

DIXON, CLAUDE F., AND OLSON, PAUL F.

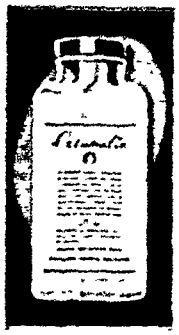
Twenty Year Cures of Carcinoma of the Colon. S. G. O., 62:874-879, May, 1936.

Hopeful encouragement is offered by considering those patients surviving operation for carcinoma of the colon rather than those dying of the disease. Reporting twelve such persons still living or having lived for 20 years after the removal of the growth is especially significant when the normal expectancy of most of the patients in this group is considered. The fact that two had additional resection of the small intestine and one of the bladder at the time of the colonic resection gives additional evidence that these cases are far from hopeless. An interesting incidental finding was the confirmation of the feasibility of grading carcinoma. Every one in this series had been graded 1 or 2. To put it another way, no patient with a colonic carcinoma graded 3 or 4 survived a 20 year period. Further, only three of the twelve cases showed metastasis to the local lymph nodes. In a study of the entire group of 453 cases, it was shown that there was an increasing incidence of local metastasis with the higher grades. In other words, that metatasis was twice as frequent in primary lesions of grade 4 than it was in those of grade 1. These findings seem rather conclusive so far as grading is concerned.

The ability to give specific instances of 20 year cures as reported in this series of microscopically proved cases should offer much consolation to patients having this type of malignancy.

J. Duffy Hancock, Louisville.

RED CROSS HEALTH WORK



WORKING in cooperation with local public health authorities the Red Cross carries on each year hundreds of immunization programs in communities threatened with serious epidemics of typhoid and other communicable diseases. An unusually large amount of this preventive work was done this year in the wide areas affected by floods. Many of these communities were without suitable drinking water in the mains for a number of days and although every precaution was taken to see that all drinking water was boiled it was deemed wise to carry on extensive immunization as a further safeguard.

In addition to its medical and health work on disaster scenes the Red Cross maintains a year-round Public Health Nursing service, which brings the visiting nurse to hundreds of small towns and rural communities where medical and hospital facilities are at a minimum. Not only through her nursing care of, but also by her instruction to mothers and girls in Home Hygiene and Care of the Sick does the public health nurse assist the country doctor to safeguard health in these sparsely populated districts.

All Red Cross services are supported by the annual membership dues of millions of Americans who join each year during the Roll Call, held from Armistice Day to Thanksgiving. Everyone is invited to have a part in the work of their Red Cross by enrolling in their local Chapter.

Creamalin

The Specially Prepared Colloidal Cream of Aluminum Hydroxide

THE REFRACTORY PEPTIC ULCER. Because of superior antacid and protective properties Creamalin has yielded results in many cases of gastric and duodenal ulcers resistant to previous therapies.

Creamalin combines with 14 times its own volume of tenth-normal HCl in one hour by physical fixation. Its action is sustained and without side-effects. Creamalin should, therefore, be the antacid of choice in all conditions where an antacid is indicated.

THE CONTINUOUS DRIP METHOD

Where the intermittency of the oral treatment is the limiting factor in obtaining maximum results and where a speedy rehabilitation of the patient is desirable the continuous drip treatment presents a more satisfactory therapy. By this method, healing of the ulcerated area is possible within 7 to 10 days!

APPARATUS FOR CLINICAL TRIAL AVAILABLE. We will gladly loan gastro-enterologists a Creamalin Automatic Drip Control and furnish sufficient Creamalin for a clinical evaluation of the continuous drip method. Correspondence is invited.

ABELL, IRVIN

The Surgical Treatment of Peptic Ulcer. Ky. Med. Journ. 34:286-290. July 1936.

The treatment of peptic ulcer is primarily a medical problem, surgical procedures being required for the complications, sequallae, and intractable chronicity. Surgery, regardless of the type of operation, should be directed towards a restoration of physiological function, free drainage of the stomach, partial neutralization of the stomach acids by intestinal alkalies, and the destruction or removal of the ulcers or ulcers. The three generally accepted indications for operation are perforation, hemorrhage, and obstruction. In acute perforation, prompt closure is the prime indication since the seriousness of the condition is controlled by the stoppage of the leak. Further procedures at such a time will depend not only upon the pathology presented, but more upon the condition of the patient. Chronic perforations, more or less successfully closed by nature, will present individual problems for treatment. Some hemorrhage will occur in approximately 25 per cent of all cases of gastric and duodenal ulcers. The immediate treatment should be rest in bed, physiological rest of the stomach, fluid and nutrition in the form of glucose and whole blood transfusions, and coagulants, chiefly fibrogen by mouth. If operation is done, destruction of the ulcer is imperative regardless of the type of procedure adopted. A single massive hemorrhage, particularly from a duodenal ulcer, is not usually an indication for operation unless other complications, as obstruction, are present.

In the surgical treatment of duodenal ulcers, simple excision alone is inadequate. Gastroenterostomy or pyloroplasty, either combined with cautery destruction of the ulcer are the usual measures employed. Resection is reserved for those cases with multiple ulcers, with calloused ulcers on the posterior wall, or with perforation into the head of the pancreas with fixation.

Gastric ulcers present the same surgical indications as do duodenal ulcers with the additional serious possibility of malignant change. Small resectable ulcers, 1 centimeter or less in size, may be treated by the conservative excision or cauterization combined with gastroenterostomy—never by gastroenterostomy alone. Larger ulcers, those with marked inflamatory deposit, those with healed perforations into adjacent structures and those with perigastric adhesions, require more radical treatment—sleeve resection, Billroth I, or the Polya modification of Billroth II where very wide resection is indicated.

Permanency of cure is dependent not only on the proper selection and proper technique of operation, but also upon the elimination of extra-gastric factors such as possible foci of infection and the adherence to correct dietary and medical supervision after the operation.

J. Duffy Hancock, Louisville.

DRENNEN, EARLE

Diet and Surgery in the Cure of Gastric and Duodenal Ulcers. South. Med. Journ. 29:699-701. July 1936.

Peptic ulcer is primarily a medical and not a surgical disease. The ideal time for medical cure is when the ulcer and the patient are both young. Two habits contributing to the formation of peptic ulcers are smoking of tobacco and drinking of alcohol; the predisposing cause, which is quite important, is the tendency towards ulcer which certain individuals inherit; and the exciting causes are hyperacidity, toxins, and neurogenic factors. Failure of medical treatment may be evidenced by disabling pain and indigestion, severe hemorrhage, perforation, obstruction, and malignant change. The aims of operative treatment of benign lesions are the proper drainage of the stomach and the lowering of acidity. The usual operations are gastroenterostomy, partial resection, and pyloroplasty.

In the Dietary **SPOTLIGHT**

In Diabetes GELATINE U.S.P.

A Safe, Tempting Form of Protein

U.S.P. Gelatine is being prescribed more and more in the diet of the diabetic... Knox Sparkling Gelatine in particular. It contains no carbohydrates, coloring matter or flavoring (as in factory-flavored jells), therefore can be used generously with complete safety.

Knox Gelatine can be employed to make a hundred and one flavorsome and appetizing dishes which add color and variety to the diabetic's usually monotonous menu. This brightens the patient's mental state. High in nutritional and caloric value, it is readily assimilated and utilized.

Quite a remarkable product—made as carefully as an ampule solution. For the diabetic, convalescent, tubercular, high protein, post-operative and infant diet where higher protein content is desirable.

KNOX SPARKLING GELATINE

KNOX SCIENTIFIC FACTS

Even the drying air is filtered... six weeks of scientific control makes Knox Gelatine bacteriologically safe.

•

Analysis
Knox Gelatine

Protein (14 amino acids) 85.0–86.0%
Calcium Phosphate 1.0–1.25%
Fat (less than) 1%
Moisture 13.0–14.0%
Carbohydrate Nil

•

Knox Gelatine contains less than half the metal content allowed by the U.S.P.... it has an almost-neutral pH. Odorless.

Of interest in the treatment of muscular dystrophy is the 25% glycine in Knox Gelatine.

While gastroenterostomy is quite satisfactory in many cases, it has a serious disadvantage in the possibility of jejunal ulcer. Partial resection is increasing in popularity, but it is yet too early to evaluate its true worth. Pyloroplasty which leaves the digestive tract more normal anatomically and which is less likely to be followed by serious sequellae appears to be the author's preference at the present time. Best results from any kind of operative treatment are expected in those cases where there is no family history of ulcer, the patient is middle-aged, the acidity is low, the emptying time slow, and the duration of symptoms and treatment rather long.

J. Duffy Hancock, Louisville.

CONNELL, F. G.

Duodenal Ulcer, Surgical Treatment. S. G. O., Vol. 62, No. 2, pp. 216-217, Feb. 1, 1936.

From a review of the development of the surgical treatment of non-resectable duodenal ulcer the author is led to believe that two operations, namely: (1) exclusion with resection of pylorus and antrum and also circumferential resection of part of the fundus, and (2), exclusion with circumferential resection of part of the fundus but without resection of the pylorus and antrum are equally satisfactory. Why then, he asks, remove the pylorus and antrum in resectable duodenal ulcer? Since it does not seem important to resect the pylorus and antrum the author suggests "partial fundusectomy." It has the advantage of leaving intact the antropyloroduodenoneuromuscular mechanism and diminishes the acid secreting area. The ulcer might or might not be resected. If there is pyloric obstruction an additional plastic operation there must be made.

The author observes that peptic ulcer is now recognized as a physiological problem in which there is a lack of balance between an agressive (acid) and a defensive (alkaline) factor.

The author is of the opinion that any operative procedure should be followed by postoperative medical management.

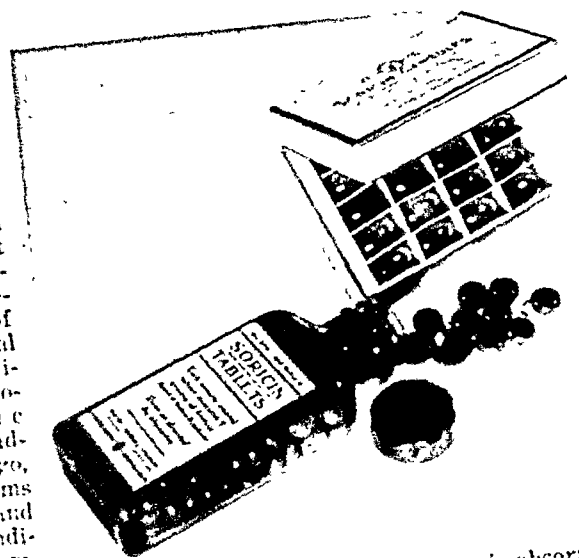
ELIASON, E. L., AND JOHNSON, J.

Life Expectancy in Biliary-Intestinal Anastomosis. S. G. O., Vol. 62, No. 1, pp. 50-56, Jan., 1936.



In a review of the experimental work done on biliary-intestinal anastomosis the author points out that ascending liver infection is an almost constant sequel. Some workers report it in 100 per cent of the cases. Others have found it less frequently.

It is generally agreed that the position of the anastomosis should be in the stomach or duodenum and not lower in the intestinal tract because the danger of infection is greater in those situations.

The operation is indicated in cases of common duct obstruction from carcinoma, chronic pancreatitis, stricture or traumatic injury of the ducts or stone in the common duct that can not be removed. Cholecysto-gastrostomy has been recommended as an alternative procedure for cholecystectomy, as a method of drainage in cases of cholangitis and in the treatment of gastric ulcer.

In cases of malignant obstruction of the common duct life expectancy may be increased by only a few months. Those few months are more bearable, however, by the relief of jaundice and its attendant discomforts. In cases of non-malignant obstruction of the common duct life expectancy may be normal. A number of patients with such conditions have died, within a few years, of ascending liver infection. Ascending liver infection is a frequent enough complication following this operation to prevent its indiscriminant

The prevention of
TOXIC ABSORPTION FROM THE BOWEL

Soricin has been used with most gratifying results for detoxification of the intestinal content. Urticaria, angioneurotic edema, headache, vertigo, certain forms of eczema and other conditions seemingly remote from the intestinal focus but definitely caused by toxic absorption, have responded to the continued oral administration of Soricin over a reasonable period of time.

Also for local conditions of the bowel, such as mucous colitis, spastic colitis, ulcerative colitis, allergic diarrhea, bacterial hypersensitivity of the intestinal tract, and intestinal toxemia, Soricin has proved itself effective in bringing relief to the patient.

SORICIN CAPSULES
Enteric coated capsules of sodium ricinoleate. Available in five-grain and ten-grain sizes.

SORICIN TABLETS (New)
Enteric coated tablets each containing five grains of sodium ricinoleate.

DIXON, C. F., AND OLSON, P. F.

Twenty Year Cures of Carcinoma of the Colon. S. G. O., Vol. 62, No. 5, pp. 674-678, May, 1936.

The authors believing that it might add to the peace of mind of those of us who may be afflicted with malignant disease in the future if more emphasis were laid on the curability of the disease and more specific instances were reported as definite proof of that contention, reports in some detail the operative and pathological records of a dozen patients who lived more than twenty years after eradication of carcinoma of the large bowel. A most exacting observer, it is admitted, might not regard these as actual cures. For those who might properly raise some question concerning the original diagnoses new microscopic sections made from the specimens after resting twenty-five years in formalin solutions have been made. Those sections confirm the original diagnoses.

Of these twelve patients, two were operated on when in their third decade; six, in their fourth decade; three in their fifth decade; and one at the age of 64. Eight of the patients were men and four were women.

In all of these cases the grade of malignancy was low. A further study of a group of 453 specimens showed the presence of metastases in the regional lymph nodes and the length of post-operative survival to be shorter in those of higher grades of malignancy. Metastases to regional lymph nodes were found to occur almost twice as frequently from primary lesions that were grade four malignancy than from those which revealed a malignancy of grade one.

Six figures accompany the article.

WILSON, W. D., LEHMAN, E. P., AND GOODWIN, W. H.

Prognosis in Gall Bladder Surgery. J. A. M. A., Vol. 106, pp. 2209-2213, June 27, 1936.

Recognition of the deficiencies of gall bladder surgery from the point of view of complete relief of symptoms has troubled both surgeons and internists. It is agreed that although the place of surgery in the treatment of a large group of cases with gall bladder disease is established, in another group the benefits of surgery are not so obvious.

Six hundred and ten cases operated on over the period of years between 1921 and 1931 by twenty surgeons at the University of Virginia Hospital were studied. The mortality rate was 3.6 per cent.

Questionnaires were sent to the patients (except the 22 who died in the hospital) and replies were received in 417 cases. The interval between the treatment and the questionnaire varied from four months to thirteen years. The patients were questioned concerning (1) general health, (2) recurrence of symptoms, (3) food tolerance, (4) hernia, (5) capacity for work, (6) their estimate of the effects of treatment.

The method used by these authors demonstrates no statistical significance in comparisons between the symptomatic results and such factors as age, sex, race, duration of symptoms, severity of symptoms, presence or absence of jaundice, presence or absence of a history of colic, the degree of functional disturbance indicated by the cholecystogram, the pathologic stage of the disease and the type of operation.

The conclusions reached are as follows:

A. Cholelithiasis presents satisfactory clinical results in 7.5 per cent of

Vesico-Intestinal Fistulae Caused by Foreign Bodies in the Bowel. J. A. M. A., Vol. 106, pp. 2125-2128, June 20, 1936.

Vesico-intestinal fistulae are of rather frequent occurrence when due to diverticulitis or malignancy, but very rare if the fistulae are due to foreign bodies. In a review of the literature it was difficult to determine whether the foreign body traveled by way of the gastro-intestinal tract, whether it became lodged in a diverticulum, resulting in a diverticulitis, adhesion to the bladder and finally perforation by ulceration, or whether the foreign body was introduced into the bladder through the urethra, and thence into the intestine.

The author reports a case of a man who for six months complained of frequency, urgency, dysuria, nocturia, hematuria, chills, fever, and had loss of 25 pounds of weight in this time. Examination revealed a large fixed mass in the median line above the pubis. Cystoscopic examination revealed a markedly injected bladder, a foreign body in the floor which when removed consisted of vegetable matter, and a brown spot on the posterior wall of the bladder with a depression in the center. This spot suggested a fistula but a catheter would not pass, and sodium iodide introduced into the bladder could not be vistualized in the intestine. Preoperatively, a diagnosis of carcinoma was made. At operation a large mass was found and removed. The center of this mass contained a large, curved, sharp-pointed chicken bone.

This is a typical case of vesico-intestinal fistulae, and shows the value of cystoscopic examination in all cases of prolonged cystitis.

Francis D. Murphy, Milwaukee.

KIPP, H. A.

Observations on the Variations in Bile Pressure in the Human Biliary Tract. J. A. M. A., Vol. 106, pp. 2225-2227, June 27, 1936.

Observations of the bile pressure in a 78 year old man were made. The patient had been jaundiced for more than two years. At operation a benign stricture of the common bile duct at the ampulla of Vater was found. A cholecystogastrostomy was performed and a T tube was placed in the common duct. The convalescence of the patient was stormy, but after about three months he was discharged from the hospital. The T tube was left intact because of the age, the general condition of the patient, and the fear of an ascending infection.

The author thought that if the pressure of the bile in the T tube was not high, and if it was no higher when erect than when laying down, the tube could be removed safely. With this in mind, he arranged a manometer with a 4 mm. inside diameter and a scale in inches, and connected it to the T tube.

The average of the pressure on inspiration was 6.28 inches (159.5 mm. of bile) and on expiration was 5.7 inches (142.5 mm. of bile). It was also noted that when the patient took a deep breath the pressure was raised on both

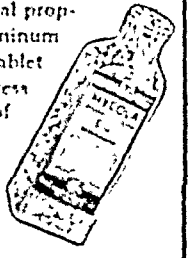
Increased Interest in

MUCIN
•
COLLOIDAL KAOLIN
•
COLLOIDAL ALUMINUM HYDROXIDE

is evidenced by the number of papers presented at various medical meetings and the amount of space devoted to these medicinals in medical publications. The KAO-MUCIN — HYCOLA combination treatment for gastro-intestinal disorders presents these well known medicaments in palatable, convenient tablet form.

Authorities are agreed that a complete and effective acid neutralization or removal program is the first step toward healing of peptic ulcer lesions.



KAO-MUCIN and HYCOLA should be used alternately; KAO-MUCIN between meals to reduce bacteria, toxins and gas, and provide a viscous protective covering over the ulcerated area: HYCOLA after feedings to reduce excess acidity by colloidal adsorption. KAO-MUCIN assists the therapeutic action of HYCOLA.

KAO-MUCIN
C. P. Co.
Concentrated Vegetable Mucinoid

Relieves gastric pain promptly and allays patient's mental distress. Provides a viscous protective coating over the gastro intestinal mucosa. Also valuable in colitis, dysentery and flatulence. One tablet will absorb app. 4 cc. of N/10 HCl. Supplied in packages of 100 tablets.

HYCOLA
C. P. Co.
Colloidal Aluminum Hydroxide

NOW — the colloidal properties of moist aluminum hydroxide in tablet form. Removes excess acidity in cases of peptic ulcers and gastric disorders *not by chemical* neutralization but by colloidal adsorption. One tablet will adsorb app. 5 cc. of N/10 HCl. Supplied in packages of 60 tablets.

Write for samples and complete information.

The Columbus Pharmacal Co., Columbus, Ohio.

inspiration and expiration. Coughing also increased the pressure to a considerable extent. Laughing also produced some rise in the pressure. The feeding of a fatty meal was accompanied by a slight rise in pressure, probably, and to increased peristalsis. After these tests were made, the patient was allowed to stand up and the pressure *rose to 13½ inches on inspiration* and 12½ inches on expiration. This elevation postponed the removal of the T tube for another year.

At this time similar observations were noted. Therefore the T tube was still left in place for another three months, at the end of which time it was removed. This was followed by a healing of the wound in eighteen days and apparently no impairment of function of the cholecystrogastrostomy.

McGOWAN, J. M., BUTCH, W. L., AND WALTERS, W.

Pressure in the Common Bile Duct of Man. J. A. M. A., Vol. 106, pp. 2227-2230, June 27, 1936.

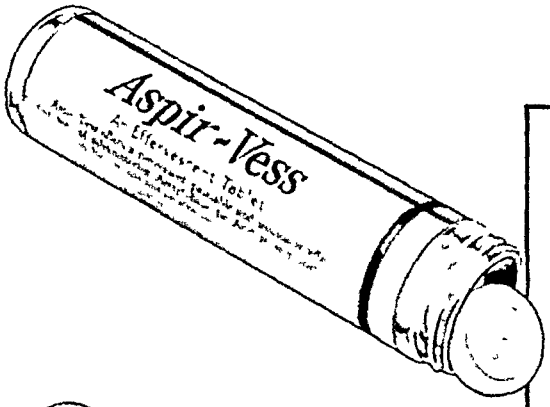
Recently the importance of the function of the sphincteric mechanism at the lower end of the common bile duct and the clinical application of the knowledge concerning it in the management of biliary tract disease have been receiving a great deal of attention.

With this in view, the authors have made a series of observations of the changes in pressure in the common bile duct on individuals with a T tube in the common bile duct for the purpose of prolonged biliary drainage. The pressure was measured by a spinal fluid manometer connected to the T tube.

Studies of the pressure were made on fifteen occasions; the subjects were eight different patients, all of whom were at rest during the studies. Respiratory excursions caused the pressure to rise from 5 to 10 mm. of water. Morphine sulfate, it was found, in doses of one-sixth grain, subcutaneously, produced an increase in intraductal pressure on fourteen occasions. The pressure began to rise in from two and a half to four minutes after the administration of morphine. In one case it was associated with constant pain. This pain became increasingly severe for the first ten minutes and was followed by a gradual decrease in severity, probably due to the action of the morphine on the higher centers.

The cause of the pain offers a large field for speculation. It was noticed, however, that fluid could be made to flow from the common bile duct into the duodenum after the administration of morphine only by increasing the pressure. Roentgenograms showed evidence of rapid emptying of the duct before morphine and distention after its administration.

It was thought that muscle spasm might be the cause of the pain. In accordance with this various drugs were administered to combat it. It was found that atropine, histamine, phenobarbital, sodium, alcohol or acetylsalicylic acid



The ABC of EFFERVESCENT MEDICATION

Aspir-Vess, Bromo-Vess, Cinsa-Vess

Three standard types of medication now presented in a more pleasing, more effective form of effervescent tablets.

Effervescence secures:

1. GREATER EFFECTIVENESS
2. INCREASED PALATABILITY
3. BETTER TOLERATION

Aspir-Vess

Combined Aspirin-Alkali Treatment in an Effervescent Tablet
A Real Pharmaceutical Achievement

Each tablet contains: Acetylsalicylic Acid (aspirin) 5 grains
Sodium Bicarbonate 31 grains
Citric Acid 21 grains

On solution in water, brisk effervescence carries the drug more quickly into the intestines, secures quicker effect, reduces possibility of gastric upset to a minimum.

Bromo-Vess

The Bromides in More Effective Form—No Salty Taste

Presents the well known triad—bromides of sodium 7½ gr., potassium 7½ gr. and ammonium 1 gr. The presence of ½ minim Fowler's Solution permits administration of large dosages with less danger of bromide rash.

Cinsa-Vess

For Rheumatism, Arthritis—Quick Symptomatic Relief

The three established anti-rheumatic agents—sodium salicylate, cinchophen, colchicine—in effervescent, alkaline solution. Secures quick assimilation, more rapid effect, better toleration.

EFFERVESCENT PRODUCTS, INCORPORATED
ELKHART, INDIANA

produced no effect. Amyl nitrite produced a fall in pressure to zero, followed by a rise to the level before the administration of the morphine. Glyceryl trinitrate produced an effect about one-third as good as the amyl nitrite.

MALS, V.

Jejunostomy as a Palliative Procedure in Inoperable Obstructive Carcinoma of the Stomach. S. G. O., Vol. 62, No. 6, pp. 960-963, June, 1936.

Jejunostomy as a palliative procedure in inoperable obstructive carcinoma of the stomach should be done only after careful exploration of the entire abdominal cavity. The author prefers the upper left paramedian incision and nitrous oxide and oxygen or ethylene anesthesia.

A loop of jejunum, usually the upper 12 inches, are sought for and delivered through the incision; care being taken to determine that its mesentery is not twisted. The Eiselsberg-Witzel type of jejunostomy is made and its upper end secured to the anterior abdominal wall at the point where it lies without tension.

No pre-operative care is required. Post-operatively water may be given in small quantities within a few hours. A diet best for jejunal digestion as outlined by Ivy should be prescribed. Aspirated gastric juices and vitamin preparations may be mixed with the pabulum. If the tube is removed accidentally it may be re-inserted readily.

Five figures and a short bibliography accompany the article.

HINMAN, F., MURPHY, W. K., WAYMAN, T. B., MCCORKLE, H. J., AND BENTEEN, F. H.

An Experimental Study of Uretero-Intestinal Implantation. S. G. O., Vol. 62, No. 6, pp. 909-917, June, 1936.

The authors, in a study designed to determine the cause of peritonitis following uretero-intestinal anastomosis, performed that operation simultaneously bilateral in a large series of dogs. Ten different methods were employed. Contamination of the operative field was made in several instances and did not seem to affect the course of the animal post-operatively. Leakage, post-operatively, at the site of direct, as opposed

THE

IMPORTANCE

of Neutralizing Acids

In acute infections—pneumonia, influenza, etc., toxic acids must be neutralized to relieve the over-taxed kidneys and aid proper elimination. Granular effervescent CAKNAM, the true systemic alkalizer, is an effective, rapid neutralizer of acids—helps to take the load off the kidneys. Rich in citrates, free from tartrates and sodium chloride. Palatable and non-laxative. Available on prescription in 5½ oz. bottles. Write for trial package and literature

TRI-CALSATE NEUTRALIZES WITHOUT HARMFUL ALKALOSIS

TRI-CALSATE is a *buffered neutral antacid* that eliminates the disadvantages of the alkaline antacids. Non-toxic—non-irritating—palatable, TRI-CALSATE does not stimulate the secretion of gastric HCl or alkalize the stomach contents.

For the distressing symptoms of peptic ulcer, heartburn, hyperchlorhydria, etc., TRI-CALSATE provides rapid relief without harmful systemic effects.

NOW IN THE NEW ECONOMY SIZE BOTTLE! The quantity in the large size bottle has been increased from 16 to 18 oz. at no increase in price, making in effect a ten per cent reduction in price to the patient.

F. H. PAXTON & SONS,

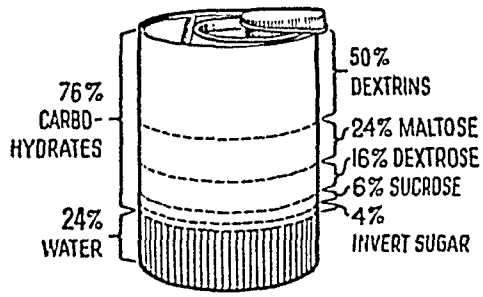
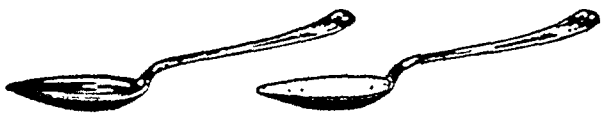
451 E. OHIO ST. CHICAGO, ILL.

Avoid the Vicious Circle of Alkali Neutralization



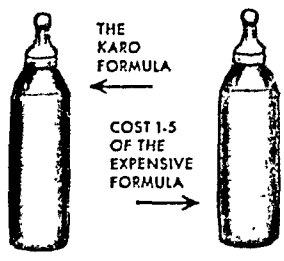
We will be pleased to send you literature and a trial supply of TRI-CALSATE, upon request.

...THE TRIPLE TEST IN PRACTICE!



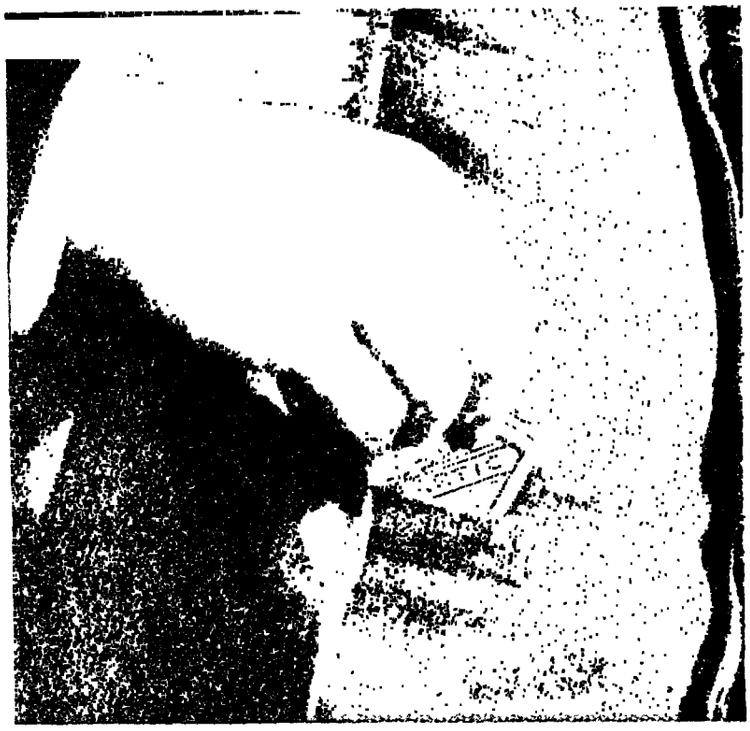
THE ETERNAL TRIANGLE dominates the lives of products, even as of men. In infant feeding the doctor is concerned with the three factors—*composition*, *concentration* and *cost!* Apply the triple test in your practice. Let us now put it to Karo:

(1) Composition...When you prescribe Karo as the milk-modifier you are providing well-tolerated, readily digested maltose-dextrins-dextrose. The dextrins are non-fermentable; the maltose rapidly transformed to dextrose requiring no digestion; the sucrose added for flavor is digested to monosaccharides. Karo is prepared chemically superior, bacteriologically safe—non-allergic, practically free from protein, fat and ash.



(2) Concentration—When you consider that volume for volume, Karo Syrup furnishes *twice* as many calories as a similar sugar modifier in powdered form, you realize *how* strongly saturated Karo is in calories of maltose-dextrins-dextrose. A tablespoon of Karo Syrup yields 60 calories while a tablespoon of powdered maltose-dextrins-dextrose gives 29 calories. Karo Syrup is a concentrated milk-modifier!

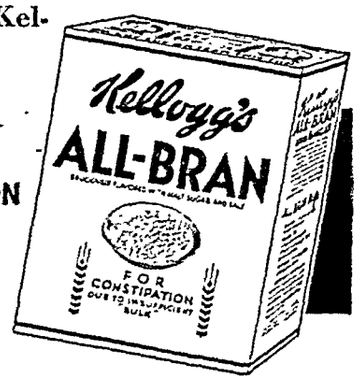
(3) Cost—When you prescribe Karo you help the family out of the economic dilemma. Karo costs 1/5 of the expensive carbohydrates, slashing the high cost of infant feedings. The maltose-dextrins-dextrose of Karo are marketed as a food. The saving is 80%. The Corn Products Refining Company charges for the constituents of Karo and nothing extra for the good name. Apply the triple test to milk-modifiers and you will find Karo desirable in composition, rich in calories, and inexpensive. Karo consists of dextrins, maltose and dextrose (with a small percentage of sucrose added for flavor).



Karo Syrup contains twice as many calories as... *Powdered Maltose-Dextrins-Dextrose including Karo Powdered*

Corn Products Consulting Service for Physicians is available for further clinical information regarding Karo . . . Please Address: Corn Products Sales Company, Dept. DN-10, 17 Battery Place, New York City.

The "vest-pocket" habit



MAY HARM MORE THAN IT HELPS

MOST doctors agree that the haphazard use of cathartics by the average person is often a contributing cause of chronic constipation.

Rather than visit the doctor, thousands of people carry around pills or tablets, taking a dose whenever they feel the need. They forget that cathartics should not be used continually, except under strict medical supervision.

By far the most common type of constipation is due to insufficient "bulk" in meals. Its correction is largely a matter of diet. The family physician, usually, is in the best position to prescribe the proper diet.

Where the diet permits "bulk," Kellogg's ALL-BRAN is doubly convenient. This delicious laxative food may be served as a cereal, or cooked into recipes. In addition to its gently acting "bulk," it supplies vitamin B and contains iron. ALL-BRAN is sold by all grocers. Made by Kellogg in Battle Creek.

The natural food THAT CORRECTS CONSTIPATION due to insufficient "bulk"

to oblique. Implantation was followed by peritonitis and death of the animal in every instance. In 23 of 53 animals rather severe infection of the abdominal wound developed and was followed by death from ivisceration, peritonitis, etc. Localized abscess around the anastomosis occurred in two instances and was the origin of peritonitis in two others.

The author concludes that leakage or contamination at the time of operation is relatively unimportant, but that leakage from sloughs or tears after operation is the chief cause of peritonitis. The oblique method of implantation is preferable to the direct method.

Two tables and eight figures acompany the article.

Nelson M. Percy, Chicago.

McNEALY, R. W., AND LICHTENSTEIN, MANUAL E.

Gastrojejunostomy Pre-operative Decompression. S. G. O., 63:96-98, July, 1936.

Poor function of a gastrojejunostomy stoma may result from the fact that the stoma is usually made in a dilated stomach where elongated muscle fibres shorten in length after relief of the obstruction. Because of this and because, further, of the difficulty presented in suturing the thickened and edematous walls of such a dilated stomach, pre-operative decompression by continuous aspiration is suggested. The proper time for operation after the institution of such drainage is indicated by the development of a "positive pyloric balance," that is, when the amount of aspirated material is less than the amount taken by mouth, showing that the stomach is normally evacuating some of its contents. During this time of preparation, the nutrition, hydration and chemical balance of the patient should be cared for. In addition to these usual measures, some benefit may be derived from the administration of 60 to 80 minims of dilute hydrochloric acid given three times a day in 30 cubic centimeters of the juice expressed from raw beef diluted with an equal amount of water.

J. Duffy Hancock, Louisville.

DONALD, J. M.

"The Treatment of Acutely Perforated Duodenal Ulcer by Excision with Pyloroplasty." South. Med. Jour., 20:827-833, August, 1936.

There is unanimity of opinion in favor of immediate operation in cases of acute perforation of peptic ulcers. Duodenal ulcers are approximately ten times as frequent as gastric ulcers in this country. True pyloric ulcers are extremely rare—when the pylorous is involved, it is usually by an extension of a duodenal or gastric ulcer. Since ten to twenty percent of duodenal ulcers perforate, and since most patients with perforation gave an ulcer history, the prevention of perforation is best accomplished by adequate treatment of the ulcer early in its history. After the catastrophe occurs, the most common surgical procedures used are (1) simple closure, (2) simple closure plus gastroenterostomy, (3) excision wth pyloroplasty, and (4) subtotal gastrectomy. Simple closure has been recommended since it is the least possible amount of operative interference that can give relief and many feel that no more should be done in these desperately ill patients. On the other hand, it can be said that the severity of the symptoms usually brings the patient to the surgeon before there is much shock, a high percentage of the patients are not permanently relieved of their ulcer symptoms, there is danger of some degree of post- operative pyloric stenosis, and closure of the friable edematous tissue is not always as simple as it sounds. Gastroenterostomy is indicated where there is marked pyloric stenosis present at time of perforation, but has the disadvantage of late complicating gastrojejunal ulcers. Partial gastrectomy is generally regarded as an unnecessarily radical procedure for the type of ulcer found in this country.

While the operative measure used should be individualized to the conditions present, local excision with some form of pyloroplasty deserves more consideration. Different types of pyloroplasty are quite satisfactory but the one devised by Judd for non-perforated duodenal ulcers and described by him as "gastroduodenostomy" seems the most satisfactory. It is applicable in most cases, since the ulcer is usually found from 1 to 1.5 c.m. from the pyloric ring, stenosis and fixation of the pylorous are usually not present, and it requires only a few more minutes than simple closure. It offers the advantages of a gastroenterostomy without the possibility of marginal ulcer, it avoids constriction of the pylorus, and it results in the removal of friable tissue which may cause subsequent leakage where only simple closure is done. The procedure consists in the excision of a rectangular area including the cap of the duodenum, the ulcer, and the anterior half of the pyloric muscle, and the restoration of the normal continuity of the gastrointestinal tract by transverse closure. The mortaliy of the series described and also that of other series treated by this or some other form of excision and pyloroplasty are appreciably less than the usual 20 to 25%.

J. Duffy Hancock, Louisville.

JACOB K. BERMAN, WITH THE TECHNICAL ASSISTANCE OF NEAL E. BAXTER

Duodenogastric Intussesception — An Experimental Study of Peptic Ulcer. Arch. of Surgery, Vol. 33, 1-18, July 1936.

In an article introducing a new experimental surgical procedure into the study of peptic ulcer the author discusses the effects of this operation upon the gastric acidity and the quantity of gastric mucin produced in the stomach of three dogs and the influence of the operation in protecting the stomach and duodenum from experimental ulceration.

The technical procedure is to produce an intussusception of the first portion of the duodenum into the pyloric end of the stomach. The pyloric sphincter is first divided and the duodenum is invaginated into the stomach to a point proximal to the ampulla of Vater. The stomach and duodenum are sutured together exteriorly in this new relationship and the patency of the canal is tested.

The purpose of this experiment is based upon the assumption that there are two functions of the secretion from the Brunner's glands of the duodenum. The first of these functions is to produce a local protective mucin and the second to produce a hormone which causes an increase of gastric acidity. Increased acidity is in turn, according to the work of Florey and Harding, thought to cause a further production of the protective mucin. Thus Brunner's glands have an important role in the control of gastric acidity as well as a profound influence upon the protective mechanism of the gastro-duodenal mucosa.

Six determinations of free and total acid and of gastric mucin were made on each of three control dogs and on three dogs after the above operation was performed. The acidities were definitely higher in those animals having had the duodenal invagination. The gastric mucus was increased grossly and was very tenacious so that ample material for study could not be withdrawn through a Rehfuss tube. This increased acidity occurred in spite of the fact that there was free regurgitation of both bile and alkaline duodenal secretions into the stomach.

In another group of experimental animals the authors produced experimental ulcers in control dogs by the administration of Cinchophen, and in some having had a Finney pyloroplasty and in others having had duodenal invaginations. Acute hemorrhagic ulcerations were produced in all control animals. Ulceration and perforation occurred in at least one dog in which a Finney operation

Dependable CHOLERESIS and CHOLAGOGUE Action

Free From Undue Purgings

Decholin augments the production of bile by the liver cells 100-200%—true choleresis. Cholagogue action follows as a direct consequence, since the increased bile flow fills the gall bladder more thoroughly, and prompts more complete evacuation. * * * *A Single Chemical Entity — dehydrocholic acid* — Decholin does not depend upon the addition of irritant cathartics for its action, nor does it produce undesirable purgings, as is the case with so-termed "cholagogues." Decholin is of proved value in chronic cholecystitis, cholangitis, hepatitis, and functional hepatic insufficiency.

Riedel-de Haen, Inc.

REG. U.S. PAT. OFF.

Exicol Background

The therapeutic effect of Exicol has been adequately demonstrated not only clinically, but in the laboratory as well. This sound, scientific background is your assurance of effectual results in prescribing Exicol in the treatment of diseases of the biliary tract.

ACTION: 1. Stimulates Gall Bladder evacuation (Cholagogue)
2. Increases bile flow from the liver (Choleretic)

Indicated in:
1. Chronic Cholecystitis
2. Cholelithiasis
3. Catarrhal Jaundice
4. Hepatitis and functional hepato—biliary disorders.

Dosage: 2 capsules, t.i.d., ½ hour before meals with liberal quantities of water.

Available: in elastic soluble capsules, boxes of 36 and 100.

Brooklyn Scientific Products Company, Inc.
80 Fourth Avenue New York, N. Y.

had been done. Only one dog upon which duodenal invagination had been performed developed an ulcer. This dog showed no increase in acidity after the operation as did all others which received Cinchophen. The authors believes that a failure to respond with an increase in gastric acidity indicates that this animal failed also to produce a sufficient amount of protective mucin, hence an ulcer developed.

They conclude that it is more likely a failure of this protective mechanism than an increase in acidity which may be responsible for peptic ulcer in man. The breakdown of this mechanism is thought to be due to an inactivity of the Brunner's glands of the duodenum. It is theorized that in the premonotory stage of peptic ulcer the administration of hydrochloric acid might stimulate these glands and increase the mucin protective activity of the gastric mucosa. It is also suggested that the operation of duodenal intussusception may become of value in the surgical treatment of peptic ulcer in man.

MACGUIRE, D. P.

Palliative Colostomy. S. G. O., Vol. 63, No. 1, pp. 66-68, July, 1936.

The author, prompted by a recent report of a seemingly inordinately high mortality rate following palliative colostomy, warns the general surgeon and occasional operator to give his undivided attention to each individual case. He points out the importance of daily blood chemistry determinations, blood cultures, blood counts, and urinalysis.

A method of palliative colostomy in which a tongue of skin, subcutaneous tissue and aponeurosis supports the exteriorized portion of bowel and prevents herniation beneath it is described.

Ten figures accompany the article.

MCNEALY, R. W., AND LICHTENSTEIN, M. E.

Gastrojejunostomy. Pre-Operative Decompression. S. G. O., Vol. 63, No. 1, pp. 96-98, July, 1936.

The authors, believing that too little emphasis has been placed on the preoperative treatment of patients with pyloric obstruction, point out some important considerations and report a means of restoring the stomach to a near normal state. Suture of a dilated, hypertrophied and edematous stomach wall is difficult and treacherous. Likewise, a gastro-enterostomy stoma in the proper place in a dilated stomach is apt to be too small and in an improper position when that stomach contracts to normal size. To decompress the stomach pre-operatively and allow it to return to a near normal state the authors have constructed a suction apparatus which is a combination of the methods suggested by Wangensteen, Bartlett, Babcock, Pratt and Peluse. By comparing the volumes of materials aspirated from the stomach from time to time with those of materials taken by mouth it will be apparent that the pyloris is either patent or closed. When the volume of material aspirated is less than that taken by mouth the "pyloric balance" is said to be "positive." Hourly recordings of aspirations and materials taken by mouth may be charted to show the status of the pyloris at any time. Operation should not be undertaken until the "pyloric balance" is 'positive."

Three figures accompany the article.

accurate or beneficial as evidenced by the variability in the time chosen by different surgeons. This article gives the result of a serious attempt to develop an organized routine post-operative study to determine the time for removal of the tube in any individual case. Some rather definite tests are described.

The food test which will result in increased biliary drainage after meals if the sphincter of Oddi does not show normal physiological relaxation is a much safer test than the frequently-used one of clamping off the tube for a period of time. Drainage, of course, must be continued until satisfactory relaxation occurs. Daily microscopic examination for pus cells is of value—drainage obviously being required as long as more than an occasional pus cell is found. A study of the crystals present in the bile sedimentation is of importance. Fragments of cholesterol crystals are strongly suggestive of the presence of a stone remaining in the duct. Calcium crystals are usually indicative of an associated pancreatitis which would be an indication for farther drainage. Any appreciable quantity of calcium bilirubinate crystals indicate a continuation of pus and a colon bacillus infection. The tube in these cases should not be removed at the disappearance of pus, but not until a marked decrease in these crystals occurs. The presence of large amounts of pancreatic ferments is a contraindication to removal of the drainag etube since painful excoriation of the abdominal wall will rerult from contact with such bile. In some cases this is the result of an anatomical anomaly but will be taken care of safely if the sphincter of Oddi functions properly.

Although of no significance in determining the time for removal of the tube, a study of the bile salt output, in conjunction with the other examinations, will indicate, when a decrease occurs, the need for active liver therapy (glucose, sodium chloride, and fluids).

J. Duffy Hancock, Louisville.

SURGERY OF THE LOWER COLON AND RECTUM

JONES, DANIAL FISKE.

"Carcinoma of the Rectum and Colon." South. Med. Jour., 29:339-344, April, 1936.

This is an unusually practical paper based on a large personal experience. A plea is made for early diagnosis and emphasis upon the comforts rather than discomforts of colostomy. Change in bowel habit or sensation, bleeding from the rectum, and any other symptom referable to the rectum or lower abdomen should be considered due to carcinoma of the rectum or colon until proved to be otherwise. The most important symptom in carcinoma of the rectum is pain evidenced as an ache or tired feeling over the sacral area or discomfort in sitting. The other significant one is bleeding. Abdominal pain due to various degrees of obstruction is especially present when the growth is in the colon. Proper digital and sigmoidoscopic examination, both of which are described, should give a correct diagnosis in 100% of the cases of carcinoma of the rectum—X-ray examination in only 40%. Not much importance is attached to the usual text-book symptoms of constipation, diarrhea, ribbon stools, loss of weight, and the age of the patient.

The operation done should be an extensive radical one. Five different procedures are named and the abdominoperineal operation in one and two stages is described. Proper preparation of the patient is emphasized. This includes preliminary cecostomy, and glucose and digitalis where indicated. Ether is the anesthetic of choice. Temporary paralysis of the bladder is an annoying post-operative symptom. The great majority of men are impotent after the operation. Operation is definitely preferred to radiation. While the value of aseptic anastamosis is appreciated, more emphasis should be placed on the preservation of the blood supply and the prevention of intra-intestinal pressure. A dry colon is a much safer one to work with than is one containing liquid feces. Some interesting personal statistics are tabulated.

J. Duffy Hancock, Louisville.

THE *Critical* PERIOD OF ADOLESCENCE

For fast-growing adolescents who must make the adjustments to increasing glandular activity and who are frequently underweight, lacking in appetite, nervous, and listless, OVALTINE has proved valuable.

Long experience has demonstrated the value of OVALTINE as a building and protective food for growing children. It is an effective aid in (a) improving appetite, (b) increasing weight, (c) reducing nervousness.

OVALTINE has an enticing flavor which appeals equally to young and old, sick and well. It adds food quality in a readily digested form, increases considerably the ease of digestion of milk, adds vital food elements such as the essential minerals, iron, calcium and phosphorus —and Vitamins A, G, D and the appetite promoting Vitamin B.

OTHER USES

OVALTINE is also valuable for convalescents, nursing and expectant mothers, and the aged. Taken at bedtime it aids in securing restful sleep.

OVALTINE

The Swiss Food-Drink

Now made in the United States

For bland diet therapy, especially ULCER cases—PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastro-intestinal disorders is a deficient diet. An analysis made by Troutt of ulcer diets used by 6 leading hospitals in different sections of the country showed them to be "well below the Sherman standard of 15 milligrams" in iron and low in the water-soluble vitamins.[1] "Vitamin B would appear to be represented at a maintenance level in most cases," writes Troutt, "but the possible relation of vitamin B to gastro-intestinal function and appetite should make one pause before accepting a low standard."

Although Pablum has a low fiber content it is 37 times richer than farina in iron and in calcium, 4 times richer in phosphorus, and 40 times richer in copper.

Low in Fiber—High in Iron

Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastro-intestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than farina and is an excellent source (+ + +) of vitamins B and G, in which farina is deficient. Supplying 8½ mgms. iron per ounce, Pablum is 8 times richer than spinach in iron.

Rich in Vitamin B

The high vitamin B content of Pablum assumes new importance in light of recent laboratory studies showing that avitaminosis B predisposes to certain gastro-intestinal disorders. Apropos of this, Cowgill says, "Gastric ulcer is another disorder which can conceivably be related to vitamin B deficiency. Insofar as the treatment of this condition usually involves a marked restriction of diet the occurrence of at least a moderate shortage of this vitamin is by no means unlikely."[2]

Requiring no further cooking, Pablum is especially valuable during the healing stage of ulcer when the patient is back at work but still requires frequent meals. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Pablum has the added advantage that it can be prepared in many varied ways—in muffins, mush, puddings, junket, etc. Further, Pablum is so thoroughly cooked that its cereal-starch has been shown to be more quickly digested than that of farina, oatmeal, cornmeal, or whole wheat cooked four hours in a double boiler (studies *in vitro* by Ross and Burrill[3]). In addition to the above advantages, Pablum is the only base-forming cereal (except Mead's Cereal which is the uncooked form of Pablum).

Pablum (Mead's Cereal thoroughly cooked) consists of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa, yeast, beef bone, iron salt and sodium chloride. [1] [2] Bibliography on request.

Washington, D. C.

President's Address*

By

HOWARD F. SHATTUCK, M.D.
NEW YORK, NEW YORK

IT has been a custom of this Society, for the President to address the Association at the beginning of each annual scientific session. First, I want to thank the Association sincerely for electing me your President last year. It is a great honor to be added to the long line of my distinguished predecessors. I also wish to express my grateful appreciation to the officers and members of the Council for all they have done to help carry on the work of the Association this past year. We are particularly indebted to our most efficient Secretary, Dr. Boles, for the great amount of time and thought he gives to our society's affairs. In addition to his many routine secretarial duties he has had the major part in arranging this year's program. I feel especially grateful to all our members for their continued interest and support which have made possible this year's promising scientific program.

I take this opportunity to extend a cordial welcome to our newly elected members, research, active and associate. The lengthening waiting list for membership makes your election at this time increasingly significant. The value and importance of this organization in its special field of medicine have been amply described by several of my predecessors in office. All the new members, I am confident, will share with the other members, a feeling of gratitude for the scientific inspiration and pleasant association that this society affords.

The addresses of former Presidents have so completely covered the general aspects of gastro-enterology and the affairs of our Association that there is little new to be said on these subjects. Then too, with such a profitable program awaiting us, I do not feel justified in delaying it with any extended remarks.

The American Gastro-Enterological Association, during its almost forty years of existence, has done much to develop the field of its special interest in America. A former President, Dr. Piersol, has well shown how gastro-enterology has become firmly established as a division of internal medicine of special interest and importance. During the period of its development there has appeared an increasing number of other medical specialties or subdivisions of internal medicine, if you will, such as cardiology, pulmonary diseases, diseases of metabolism, allergy, endocrinology and, more recently, hematology and arthritis, not to mention them all.

In recent years we have heard much about the necessity of intensive specialistic training and experience for men wishing to enter one of the medical or surgical specialties. We should continue to stress the equally urgent necessity, for those entering the medical specialties, of becoming and remaining competent and experienced internists. This applies particularly to the field of gastro-enterology. In fact, very many members of this Association are most competent and eminent internists with a special interest in gastro-enterology. Some of them prefer to be considered as internists solely and simply. This, of course, is not a new thought. Many of my predecessors have emphasized it in their introductory remarks. This is, I believe, what Dr. Samuel Meltzer had in mind when, as our President thirty-three years ago he said, "While there may be some doubts about the desirability of too great a division of labor in the practice of medicine, there can be no doubt about the desirability of the division of labor in the study of the science of medicine. If we build up this Association on a high, ideal, scientific basis and develop it along these lines we shall dispell distrust and attract the best workers in this field."

On this same point, in his Presidential address before the society, Dr. Piersol ably said, "The gastro-enterologist who is worthy of the name, must first of all be a thoroughly trained, broad-minded physician. This is one of the strongest arguments against men taking up gastro-enterology or any other special branch of internal medicine before they have received a broad, general medical training. It can be truly said that although a good internist may be a poor gastro-enterologist, a good gastro-enterologist must never be a poor internist."

In a symposium on abdominal symptoms at the Southern Medical Association, Dr. Thomas R. Brown aptly put the matter as follows: "Man is an entity, not a summation of his organs and his systems, however carefully each of these be studied separately. Add together the findings of an eminent specialist in every field and you will not get the clinical picture of the case, for the organism is not the mere sum of its constituent parts. To be understood it must be studied, *soma* and *psyche*, as a whole, for no two men are alike morphologically, physiologically or psychologically."

I need develop this thought no further. My plea is that we become as competent, skilled and experienced internists as we can, and that we strive to continue so. If at all possible we should continue to examine and treat patients with cardiac, pulmonary, blood and renal disease. I am sure that as a result we will give better, wiser and safer service to the patients we see in the hospital or in private practice. We shall likewise thus avoid the pitfalls of narrow specialization, or as someone has well put it, "of knowing more and more about less and less."

There are two practical steps we might take as an Association along these lines. First, in electing new, active and associate members, we can pay even more attention to the clinical qualifications of our candidates than we have perhaps in the past. In addition to requiring an interest in the aims and purposes of our Association, and contributions to the literature, could

*Delivered at the Thirty-Ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936.

we not give added attention to the clinical training, ability, and skill of prospective members? Secondly, as has been suggested before, could we not include in our membership some outstanding, capable clinicians who have not necessarily written papers or done research? If we took these two steps, I believe our Association would increase its prestige, influence and usefulness.

Cholesterol Metabolism in Jaundice*

By

S. ALLEN WILKINSON, M.D.
BOSTON, MASSACHUSETTS

STUDIES in cholesterol metabolism are becoming increasingly complex as the subject is explored by different investigators. The level of blood cholesterol is known to be affected by variations in the function of the pituitary, thyroid, gonads, pancreas and adrenals. Disturbances in blood cholesterol values have been reported in hypo- and hyperthyroidism (1), vitamin A (2), C (3) and D (4) deficiency, diabetes (5), tuberculosis, nephrosis and amyloidosis, fevers (6), epilepsy, pregnancy, liver disease, gall bladder disease, arthritis, leprosy (7), and arterioschlerosis. In addition, Berman (2) has called attention to a syndrome of asthenia and cholesterol deficiency which he terms *asthenia cholesteropriva.*

The relationship of cholesterol esters to total cholesterol has been thoroughly studied. The variations of the cholesterol—cholesterol ester ratio in disease, and particularly in liver disease have been described by Thannhauser and Schaber (9), Epstein (10), Laroche, Griant and Costes (11) and others. It is accepted that the esters are lowered in parenchymatous liver disease, but Hawkins and Wright (12) feel that this lowered ester ratio is not a valid index in differentiating obstructive from toxic jaundice. They point out, as have other investigators (11), that liver infection, superimposed on obstructive jaundice promptly lowers blood cholesterol and the ester ratio.

AUTHOR'S STUDY

The purpose of this paper is to demonstrate some of the changes that occur in liver disease in the level of the bile cholesterol and its relation to the blood cholesterol variations. Since all the cholesterol in bile is in the form of free cholesterol (13), no attempt has been made to include cholesterol ester determinations of the blood, and all figures for blood cholesterol refer to the total blood cholesterol. The procedure for blood cholesterol determinations was after the method McClure and Huntington (14). The bile cholesterol was determined by Bloor's (15) method. Repeated examinations on the same bile specimen showed results which checked within 10%, and this was felt to be sufficiently accurate for our purpose. All determinations were done at the laboratory of the New England Deaconess Hospital.

The determinations of bile cholesterol were made on "C" bile, bile obtained either by duodenal tube after the dark "B" fraction had been discarded, or bile obtained from fistula or from a T tube in the common duct after operation. The normal bile cholesterol is a somewhat variable figure, but we feel that any values between 20 mg. and 50 mg. per cent can be assumed to be in the normal range. McClure and Vance (16) find the average normal to be 25 to 48 mg. per cent.

Table I shows the variation of blood and bile cholesterol in *obstructive jaundice.* In some of these cases there was no jaundice and no elevation of blood bilirubin at the time these determinations were made. They were included in the series, however, because of other factors which made them of interest.

In those cases with long standing obstructive jaundice, bile obtained from the common duct within one or two days after operation shows a low cholesterol and the blood cholesterol is elevated (Cases 1, 2, 3). Case 3 had had jaundice for only eight days and the bile cholesterol is only slightly depressed; the blood cholesterol is normal. Cases of intermittent jaundice due to a common duct stone (Cases 4, 5, 6) showed a normal or an elevated bile cholesterol and a normal blood cholesterol. Case 7 had an external biliary fistula and a complete stricture of the common duct. Both the bile and blood cholesterol are normal, although there was no bile passing into the intestinal tract, and consequently no reabsorption of cholesterol from this source. This has been described as a conservative mechanism and necessary to preserve the normal balance of cholesterol in the body. Case 8 also had an external biliary fistula with intermittent jaundice. The blood bilirubin was normal at the time this observation was made. This case is interesting in that she had severe hyperthyroidism and this condition is reflected in the elevated bile cholesterol and the low blood cholesterol. Case 9 had gall stones and common duct stones but was not jaundiced. She had a severe spontaneous myxedema and showed a low bile cholesterol with a high blood cholesterol. After four months treatment with thyroid the blood and bile cholesterol figures are normal and her general condition had improved sufficiently to permit operation. The presence of the stones in the gall bladder and the common duct did not influence the cholesterol values.

In the *toxic jaundice group* are included two cases of unusual interest. Both were cases of severe toxic hepatitis, one of which recovered and the other died (Cases 10 and 11). The three determinations of bile cholesterol in the case which recovered gave low figures, while the blood cholesterol was elevated. The case who died showed a progressive fall in the level of

blood cholesterol over a twenty-four day period of observation. The last blood sample for a cholesterol was taken on the day of her death. Two attempts were made during her illness to obtain bile by duodenal drainage, but there was no bile in the duodenum. The one bile cholesterol determination was made on bile obtained from the common duct at autopsy and we were much surprised to find a bile cholesterol value of 54, more than twice the blood cholesterol figure taken only three hours previously while she was still alive.

Case 12 was a very severe toxic jaundice complicating ulcerative colitis. The one bile determination seemed to be all that the patient's condition would allow. His blood cholesterol was high (300 mg.) and the bile gave a low figure. Because of the high blood cholesterol we felt the prognosis in his case was better than the clinical condition seemed to warrant, and he justified this by recovering from the jaundice although he died some months later from his colitis.

Case 13 was an early catarrhal jaundice in a young girl. The jaundice cleared rapidly and because of the unusually high bile cholesterol we suspected hyperthyroidism. The low blood cholesterol is additional indirect evidence. She later became much more nervous and showed unmistakable signs of hyperthyroidism, but we were unable to get a metabolic rate determination to confirm the diagnosis.

In case 14 the diagnosis, confirmed at operation, was chronic cholangitis. The patient had had repeated attacks of painless jaundice following a cholecystectomy some months previously. There were no stones in the common duct, and no obstruction in the ducts or at the sphincter of Oddi was demonstrated. The duodenal drainage was done during one of the episodes of jaundice. While the bile cholesterol is low, the blood cholesterol is within the normal range.

In the previous cases we have mentioned the variations in blood and bile cholesterol due to thyroid dis-

ease. Hurxthal (1) has showed very clearly that the *blood cholesterol in hyperthyroidism* is lowered below its normal level and rises to normal as the disease is controlled. He has also shown that in myxedema the blood cholesterol is elevated, and has postulated the fact that if the blood cholesterol is not elevated, even though the basal metabolism be low, the condition is not one of clinical myxedema, and is not benefited by thyroid medication. In the course of these studies, duodenal drainages were carried out on several cases of hyperthyroidism and of myxedema.

TABLE III
Hyperthyroidism

No.	Cholesterol mg. per 100 c.c.		Remarks
	Bile	Blood	
1.	88	152	Before operation
2.	42	150	Before first stage
	90		Before second stage Severe Toxicity
3.	68	128	Before operation
	25	210	Six months after operation
4.	90	122	Before operation
5.	68	134	Before operation

Table 3 shows the bile and blood cholesterol values in a small series of proven cases of primary hyperthyroidism. Other studies, not included in these tables, demonstrate that the same ratio exists in adenomatous goitre with secondary hyperthyroidism. Note the lowered blood cholesterol values and the uniformly elevated bile cholesterol. After operation these figures return to normal (Case 3).

Table IV shows the reverse of the picture seen in *hyperthyroidism*. The blood cholesterol values are high and the bile cholesterol values are all much below normal. After a suitable period of thyroid medication these figures tend to return to normal levels. These statistics clarify the abnormally low and the abnormally high values found in some of the patients with various types of liver disturbances, associated with thyroid disease, and tend to confirm the statement of Stone (18) that the thyroid is the "master regulator" of cholesterol metabolism in the body.

COMMENT

In obstructive jaundice the general trend is toward an elevation of blood cholesterol so long as there is no superimposed liver infection. If the obstruction is complete and of long duration the bile cholesterol drops to a low figure, but if it is incomplete or intermittent, bile cholesterol is normal or only slightly below the normal level. As soon as infection supervenes, both the blood and bile cholesterol are depressed, and the degree of this depression is a fairly good index of the extent of the liver involvement.

In toxic jaundice these disturbances of cholesterol metabolism vary with the severity of the condition. So far as we may draw any conclusions from such a limited number of cases, it seems that the blood cholesterol tends to remain at or near the normal level in the less severe cases and such a normal level allows a better prognosis than a very low figure. On the other hand the bile cholesterol is depressed and shows little tendency to return to normal values for some time. In the one fatal case in this series, there was a steady fall in the blood cholesterol. We have no adequate explanation for the unusual finding of a high cholesterol content in the post mortem specimen of bile.

The role of the thyroid as a regulator of cholesterol values, both in the blood and bile, is an interesting one. Jaundice with greater or lesser degrees of liver damage is a not uncommon accompaniment of severe hyperthyroidism, and some speculation is permissable as to the part played by the thyroid in producing some of the variations seen in cholesterol metabolism in liver disease. As an hypothesis which remains to be proved, it may be suggested that there is a reciprocal relationship between the liver and the thyroid as far as their cholesterol regulating mechanism is concerned. If such a relationship exists, when the thyroid is diseased the liver then eliminates either an abnormally great or an insufficient quantity of cholesterol in the bile, and the balance is disturbed. When the liver is diseased, the thyroid is unable to preserve the normal ratio between the cholesterol circulating in the blood and the cholesterol eliminated by the bile. This usually results in an elevation of the blood cholesterol. But when the liver damage is severe, the mechanism is thrown so far out of balance that the synthesis of cholesterol is seriously interfered with and blood cholesterol falls.

SUMMARY

In obstructive jaundice blood cholesterol rises while bile cholesterol is normal or low depending on the completeness of the obstruction and its duration.

In obstructive jaundice with liver infection, both blood and bile cholesterol are low.

TABLE IV
Hypothyroidism

No.	B.M.R.	Cholesterol		Remarks
		Bile	Blood	
1.	—32	6	390	Spontaneous myxedema
2.	—38	6	446	Cretirism
			176	After Thyroid
			156	After Thyroid
	—2		146	One year later
3.	—24	18.5	236	Had been on thyroid for 2 years
4.	—24	9.5	358	Spontaneous myxedema Common duct stones
	—2	48.0	180	4 months on thyroid
5.	—39	14	314	Spontaneous myxedema
		38	115	2 months on thyroid
6.	—27	trace	455	Post-operative myxedema
	—9	16	182	6 months on thyroid
7.	—23	8.1	166	Total thyroidectomy for heart failure
	—22	14.0	177	Receiving ½ gr. thyroid daily

In toxic jaundice the blood cholesterol is normal or low depending on the severity of the disease. Bile cholesterol is uniformly low and remains low after the condition has apparently cleared up.

Hyperthyroidism causes an elevation of bile cholesterol approximately in proportion to the depression of blood cholesterol.

Myxedema produces a low bile cholesterol and a proportionate elevation of blood cholesterol.

DISCUSSION

DR. ANDREW C. IVY (Chicago, Illinois): I think it is established both experimentally and clinically that in hyperthyroidism the blood cholesterol value is decreased; also, that in hypothyroidism, clinical or experimental, the blood cholesterol is increased. Experimentally, we are certain that various hepatic disorders lead to alterations in blood cholesterol, but, as Dr. Wilkinson has pointed out, this occurs, unfortunately insofar as the diagnostic value of blood tests are concerned, in other diseases.

In regard to the effect of the thyroid on the cholesterol output into the bile, I think Dr. Wilkinson's work is very suggestive to one working in the experimental laboratory. Insofar as I am aware, no one has administered thyroid extract to biliary fistula dogs to ascertain the effect upon the elimination of cholesterol in the bile, nor has anyone removed the thyroid gland from a biliary fistula dog.

If we had such results, I should be more willing to place importance upon the clinical findings of changes in bile cholesterol in the patients which Dr. Wilkinson has presented.

However, the idea of there being a reciprocal relationship between the thyroid and liver in the metabolism of cholesterol is very interesting, and I hope it will be studied further.

So as I know the physiology of the liver and biliary tract, the most serious diagnostic problem is the differentiation, particularly in the absence of the gall bladder, between an obstructive jaundice and intrahepatic jaundice. I say it is a serious diagnostic problem because if the patient has obstructive jaundice he should be operated, but, if the jaundice is due to an intrahepatic disturbance and not to an obstructive disturbance, then injury of the patient would be inflicted by an exploratory operation.

With the problem in mind, during the past year, we have been trying to find out if a study of serum phosphotase might help in making such a differentiation.

It would appear if Dr. Wilkinson's observations obtain on a large series of patients that we have the solution of this very serious diagnostic problem, namely, that in obstructive jaundice, pure and simple, we should find a high blood cholesterol. If the jaundice is due to some intrahepatic disorder the blood cholesterol should be low; or, if due to an infectious or toxic hepatic disorder in conjunction with an obstructive jaundice, then we should find a normal or low blood cholesterol.

Obviously, if this is borne out by experimental and clinical work, such will be a very important contribution. I hope that this investigation will be continued.

Dr. Wilkinson indicated that the cholesterol in duodenal fluid in obstructive and toxic jaundice is low. It is known experimentally that if we produce an obstruction, and it does not have to be a complete obstruction, a white bile, or a bile low in pigment is secreted, and when we analyze such bile for cholesterol, we find that it contains relatively little.

The same thing is true when we produce an infectious or a toxic jaundice. Such is at least true for a certain stage of toxic jaundice; whether it is true of later stages, when regenerative changes are occurring in the liver, I am not so certain. In interpreting and applying Dr. Wilkinson's results, I think we should bear in mind the fact that one may observe changes in blood cholesterol in conditions other than obstructive jaundice, and hepatic and thyroid disorders.

DR. ABRAHAM LEON GARBAT (New York City): The problem that Dr. Ivy has brought up, namely of having in jaundice some means to differentiate those cases that are surgical from those that are medical, has been a subject that my associate, Dr. Harry Jacobi, has been studying at the Lenox Hill Hospital for the last five years. We have tried the cholesterol method, we have tried the fibrin method and recently have studied the problem of the sugar tolerance curve as a method for separating the toxic medical jaundice cases from the obstructive surgical ones.

We give our jaundice patients 100 grams of glucose on an empty stomach. We examine the sugar content of the blood before the sugar intake and again three-quarters of an hour after and again two hours after. We found very striking curves.

(Slide) The cases of toxic jaundice (catarrhal, acute yellow atrophy, arsenic, etc.), show a curve which begins at a fairly normal level and remains at a fairly normal level at ¾ hr. and 2 hrs,. or rises abruptly in ¾ hr. and comes down again in 2 hrs. The first occurs in the more severe toxic cases,.the latter in the less toxic. These curves are uninfluenced by the degree of jaundice as estimated by the icteric index.

In the cases of obstructive jaundice (obstructive either in the common bile duct as due to stone or stricture, or from obstruction at the head of the pancreas, or the intrinsic hepatic group of obstruction caused by cirrhosis or carcinomatosis or abscess) we found an ascending type of curve; *i.e.* the blood sugar at the end of ¾ and 2 hrs. continues to go up and does not come down. It makes no difference whether the fasting blood sugar is within the normal limits or higher than normal, the ascending nature of the curve is the same.

DR. SIEGFRIED J. THANNHAUSER (Brookline, Boston, Massachusetts): It has been about 13 years since my coworker, Schaber, and I described the relation between cholesterol and cholesterol esters and the fact that this ratio is changed in liver diseases. The investigation was based on a series of experiments on cholesterol balance. We thought at this time that the intake of cholesterol and the output of cholesterol could be balanced in determining the cholesterol content of the food and the output in the feces.

This idea with reference to a complete cholesterol balance is unrealizable. My former collaborator, Berta

Ottenstein, showed that cholesterol is destroyed and disintegrated by bacteria in the bowels. It is not widely known that cholesterol molecules are synthesized in the body, but body functions cannot destroy the cholesterol molecule. However, cholesterol is easily destroyed in the bowels by colon bacilli. The bacilli destroy what the human body cannot do within its intermediary metabolism. The same situation exists in uric acid metabolism. The body is able to synthesize the purin ring but cannot split off the ring system.

In view of this fact, the very interesting findings of Dr. Wilkinson who compares cholesterol concentration in the blood and the cholesterol in the bile may not have in every case but one meaning. According to the fact that bacteria destroy cholesterol, a decrease of cholesterol in the bile could be produced by bacterial action in an infected gall bladder.

Another thing that I would say is about the influence of thyroid on the cholesterol excretion. Cholesterol is excreted by the bile and, to a large extent, by the intestines as Zenke and I showed in bile fistula experiments. Thus the relation between bile cholesterol content and blood content moves not in a single track. There is a very important way of excretion to the bowels where greater amounts of cholesterol are excreted. Studying the influence of thyroid medication upon cholesterol output the cholesterol values should be compared not only from blood and bile but, of course, the cholesterol output in the bowels must be considered. In the bowels, however, cholesterol is disintegrated by bacteria so that we cannot attain a real and complete cholesterol balance which will show the effect of a medication on cholesterol output.

Nevertheless, Dr. Wilkinson showed an interesting way to approach the question of cholesterol metabolism.

DR. CARL H. GREENE (New York City): This study by Dr. Wilkinson is very interesting, though it is unfortunate that more reference was not made to the relation of the gall bladder to this picture. It is well recognized that gall bladder bile is more concentrated than hepatic duct bile but in addition the cholesterol is very much more concentrated than are the other constituents. Dr. Wilkinson has tried to eliminate the gall bladder effect.

On the other hand, the study of a series of cholecystectomized patients shows that after cholecystectomy, the bile remains dilute, and the cholesterol is low in the patient with no symptoms in whom there is no residual stasis in the common duct. If there is stasis in the common duct after cholecystectomy, then one may get dark concentrated bile on duodenal drainage.

In such patients, the cholesterol in bile from the common duct increases markedly. Under these conditions it is suggested that the common duct takes over the concentrating function that formerly was possessed by the gall bladder.

Strikingly enough, in Dr. Wilkinson's chart, the cases where the bile cholesterol was high were associated with gall stones in the common duct. Before his results are accepted unequivocally we must be sure that this accessory effect of stasis in the common duct and change in the function of the common duct epithelium is considered.

DR. S. ALLEN WILKINSON (closing the discussion): I wish to thank the speakers for their comments.

Dr. Thannhauser mentioned the fact that infection of the bowel may change the biliary content of cholesterol. That, of course, probably does take place, but in those cases which were obviously infected and in those cases where there was no infection that we could demonstrate, the cholesterol content of the bile was approximately the same.

Dr. Greene raised the question of the content of the cholesterol of gall bladder bile as compared with cholesterol in liver bile. We carried out cholesterol determinations on the "B" bile, or gall bladder bile, and found that it was approximately twice that of "C" bile. Those results are not included in this paper.

It seems unlikely that the presence of the gall bladder can greatly alter the concentration of cholesterol in the liver bile, since we found approximately the same values of liver bile cholesterol in those cases who had had their gall bladders removed or who had an external biliary fistula as we did in those cases where the gall bladder was present.

Biliary Stasis*

By

CARL H. GREENE, M.D.,

J. RUSSELL TWISS, M.D.

and

R. FRANKLIN CARTER, M.D.

NEW YORK, NEW YORK

THE development of the modern point of view regarding the treatment of diseases of the gall bladder has passed through several stages. Initially came the recognition of the possibility of surgical intervention, the development of the necessary surgical technique and the establishment of the superiority of the operation of cholecystectomy over cholecystostomy. Numerous surgeons have reported surgical statistics showing the almost uniformly good results obtained by cholecystectomy in cases of acute cholecystitis and of chronic cholecystitis with stone.

The extensive study of diseases of the gall bladder stimulated by these observations led to the recognition first, of the fact that many patients with chronic digestive ailments suffer from a chronic cholecystitis without stones, and second, that in such patients the results of cholecystectomy are often disappointing.

Three factors, metabolic disturbance, infection and biliary stasis, are generally accepted as of prime importance in the development of cholecystitis or cholelithiasis and the production of the associated symptoms. The relative importance of each is by no means established. The typical biliary colic usually is indicative of gall stones but the pathologists have empha-

Delivered at the Thirty-Ninth Annual Session of the American Gastroenterological Association, Atlantic City, N. J., May 4-5, 1936.

Approved by the Committee on Publications.

sized the frequency of "silent gall stones." Many patients with non-calculous disease complain of colic. While disturbances in cholesterol metabolism are cited to explain the origin of cholesterol calculi, they do not explain the associated symptomatology. Apart from biliary colics, the chronic indigestion which Monyihan long ago described as the inaugural symptom of gall stones is now generally ascribed to an associated cholecystitis and so to infection.

The *rôle* of infection in chronic gall bladder disease is obscure. Rehfuss and Hanssen and Yurevich have reviewed this literature within the past year. They pointed out the relatively small proportion of cases in which evidences of infection in the gall bladder or its contents can be demonstrated by bacteriological methods. Andresen explains this discrepancy as due to the fact that the gall bladder inflammation is only a part of a general chronic infection of the whole gastro-intestinal tube and its appendages. He stresses the importance of coincident infection of the stomach, duodenum, liver, pancreas, appendix and colon.

Other investigators, as Jones, have shown that many of the sensations, nausea, vomiting, distension and the like, of which these patients complain, can be duplicated by inflation of a balloon in the duodenum. The symptoms of the patient with cholecystitis therefore are explained as due to interference with the normal motor function of the pylorus and duodenum produced by reflexes arising in an inflamed gall bladder. Still another alternative is the view recently discussed by Ivy that this same symptomatology may be produced by stasis within the gall bladder or bile ducts as a result of disturbance in the normal motor function of this viscus, the so-called "biliary dyskinesia."

Biliary stasis alone is insufficient to produce calculi, and calculi have been observed under conditions which seem to preclude the presence of stasis. Stasis, however, serves to provide a favorable environment for the deposition of calculi and so augments the effects of associated infection or metabolic disturbance. The importance of such stasis has not received due recognition in the past.

A consideration of the factors controlling the filling and emptying of the normal gall bladder and of the possible disturbances therein has indicated that at least three types of disturbances productive of stasis and an associated symptomatology can be recognized clinically. These types are of importance both in diagnosis and treatment.

1. Obesity and a loss of muscle tone is observed in many women as the menopause is approached. Numerous observers and, most recently Alvarez and Vanzant, have emphasized the increasing proportion of cases of achlorhydria that are observed in older people. The presence of acid chyme in the duodenum not only causes a relaxation of the sphincter of Oddi but stimulates evacuation thus resulting in distension of that viscus. This may be referred to as an *atonic distension*. The resultant biliary stasis is signalled clinically by epigastric or hypochondric soreness or distress which is most marked during fasting. Colics are very infrequent. Achlorhydria or hypochlorhydria is shown by gastric analysis. Gastro-intestinal roentgenograms are usually normal. The shadow of the gall bladder in the cholecystogram is distended and atonic may show delay in either filling or emptying. Duodenal drainage may procure a large quantity of concentrated bile but frequently this is secured only after stimulation with olive oil. The biliary stasis is further shown by the presence of crystalline sediment. Such cases respond to therapeutic management with a stimulating diet and the administration of hydrochloric acid, a fatty diet or of olive oil between meals to stimulate evacuation of the gall bladder.

2. It has long been known that in a number of cases of duodenal ulcer the symptoms are those of gall bladder disturbance. In a further number of cases roentgen study of the gastro-intestinal tract shows a duodenitis, periduodenal adhesions, pylorospasm, gastric ulcer or the like, in association with disease of the gall bladder. In such cases it can be assumed that the increased motility and tone of the duodenal musculature and sphincter of Oddi interfere with the normal evacuation of the gall bladder. Because there is an increased resistance to its emptying, the gall bladder becomes distended and hypertonic. This may be refered to as a *hypertonic* or *spastic distension* of the gall bladder. Clinically it is characterized by frequent attacks of colic which may be accompanied by jaundice. Gastric hyperacidity usually is present. Roentgenograms of the gastro-intestinal tract show evidences of pylorospasm and spasm, hypermotility or increased tonus of the duodenal musculature. Cholecystograms show the gall bladder to be distended and hypertonic. Duodenal drainage shows evidence of stasis in the frequency in which concentrated bile is procured only after stimulation with olive oil. The bile is dark and concentrated and the presence of crystalline sediment is further evidence of the stasis. Such cases respond to therapeutic management with diets of the modified ulcer type, antispasmodic drugs such as belladonna, and alkalies to control the hyperacidity.

3. The association of symptoms of gall bladder disease with neuroses of various types is no new observation. The association of chronic appendicitis, a spastic colon, pelvic disease or pregnancy, with exacerbations of the symptoms of biliary stasis has been explained on a reflex basis. In such cases it may be assumed that there is a spasm of the sphincter of Oddi as a result of vagal stimulation which may arise directly in the central nervous system or reflexly in some other portion of the abdominal cavity. This spasm or increased tonus of the sphincter of Oddi interferes with the normal evacuation of the gall bladder which then becomes distended. This may be referred to as a *neurogenic* or *vagotonic distension* of the gall bladder. The resultant biliary stasis is characterized clinically by the presence of psychogenic factors or sources of reflex irritation which may explain the vagotonia. Biliary colic and even jaundice may occur. The gastric acidity is usually within the normal range and gastro-intestinal roentgenograms do not show evidences of local lesions in the stomach or duodenum. Cholecystograms show the gall bladder to be distended and hypertonic. Duodenal drainage shows evidence of stasis in the concentration of the bile and the presence of crystalline sediment. Concentrated bile, however, is usually obtained after stimulation with magnesium sulphate solution. Such cases respond to therapeutic management with change of environment, mental rest, sedatives, anti-spasmotics, and saline cathartics. It is this group in particular that is responsible for the vogue of "spa" therapy in the treatment of cases of chronic cholecystitis.

The evaluation of the exact *rôle* of the individual factors mentioned in the production of gall bladder

disease is difficult but the concept of biliary stasis explains many of the clinical features of this disease. Failure to correct the stasis is responsible for many of the cases of recurrence of symptoms following cholecystectomy. Biliary stasis, however, is not a single disease entity but may be the result of various types of disturbance in the motor activity of the gall bladder and biliary tract. These three main types at least can be recognized. The recognition of these types permits both a more accurate diagnosis and a more specific and satisfactory therapeutic management of the individual patient.

DISCUSSION

DR. CHARLES GORDON HEYD (New York City): The authors make positive statements and submit them to a critical analysis. They say that the *rôle* of infection in chronic gall bladder disease is obscure. That is not so. You might just as well say that because a man was shot through the chest with a bullet and you failed to recover the bullet, therefore you cannot interpret the damage. You can interpret the damage of infection in gall bladder disease irrespective of the finding of the bacteria.

After a consideration of the factors controlling the filling and emptying of the gall bladder the essayists allege that variations in these factors, with stasis, produce three types of gall bladder disturbances with a symptomatology that can be clinically recognized.

This morning I have put all of their descriptive terms into parallel columns. All of these gall bladders were distended. The first is called hypertonic or spastic gall bladder distention. The second is a vagotonic gall bladder distention and the third is an atonic gall bladder distention. The first group is based on the major pathology of the duodenal tract—ulcer, duodenitis, diverticulitis. The second group is based upon pathology in the colon, chronic appendicitis and pregnancy. While pregnancy without the benefit of clergy may be associated with nervousness and apprehension, its etiology is not neurogenous.

In all three groups, the X-rays showed filling delay of the gall bladder; the "drainage" all showed concentrated bile after olive oil, or concentrated bile after magnesium sulphate, and all showed crystalline sedimentation.

I submit that the designation of these conditions has not been proved and that the descriptions are interesting, if true.

These statements do not militate against the *rôle* of stasis in gall bladder disease. At what point does physiological stasis become pathological? That is the question! To lug in a duodenal ulcer, duodenitis, chronic appendix, pregnancy, pelvic pathology and say that these conditions produce three types of gall bladder disease, each with a definite pathological and clinical symptomatology, I think is straining far beyond even the erudite resources of chemistry.

The Treatment of Acute Hepatic Insufficiency and its Relation to Prognosis*

By

CHESTER M. JONES, M.D.
BOSTON, MASSACHUSETTS

THE difficulties that surround the making of an accurate prognosis in patients suffering from severe liver disease are still extremely great. It is with this in mind that a review is made of 83 cases of severe liver insufficiency. Comments on clinical and laboratory findings and their relation to prognosis and treatment will be presented.

Fifty-six cases taken from the records of the Massachusetts General Hospital since the year 1922 were considered as being of sufficient severity to warrant a diagnosis of acute liver insufficiency. In many instances the diagnosis of acute yellow atrophy was made and substantiated by autopsy. As far as one can judge by clinical and laboratory methods, the individual cases did not vary greatly in severity during the different years. An additional group of 27 patients, all of whom had liver insufficiency of a somewhat less degree, but associated with a known cause, are included for comparison. The term "acute yellow atrophy" in reality describes a histological picture, an end process of severe liver disease due to one of many causes and in that sense is not a clinical entity. It is for that reason that the term "acute liver insufficiency" has been employed in this discussion.

The group of 56 patients whose findings are given below practically was unselected. It includes cases of alcoholic cirrhosis, toxic cirrhosis, "catarrhal" jaundice, arsenical jaundice, cinchophen jaundice, jaundice following severe sepsis, a certain number without any known cause but presenting extreme liver insufficiency, and a small group associated with cholelithiasis and severe obstructive jaundice. (Table I). All of these patients had in common the finding of intense jaundice and all were so critically ill that survival was problem-

atical in each instance. As a measure of the severity of each case attention has been paid to the intensity of the jaundice, enlargement of the liver and spleen, the presence of ascites, edema and purpura. Laboratory findings that were particularly noted included quantitative bilirubin determinations, dye retention tests and a search for occult blood in the stools. Other laboratory determinations were made on many of the patients but will not be discussed in this communication.

It is of interest to note that of the 10 patients seen between 1922 and 1925 there was only 1 survival. Of the 14 patients seen between 1926 and 1929, all died. The average mortality of these eight years is 95 per cent. In the past six years, 32 additional cases have been followed with 20 deaths, a mortality of 63 per cent. (Table II). The striking difference between the mortality of the past six years and that of the preceding eight years is sufficiently great to warrant discussion in spite of the relatively small number of cases.

In the hospital records one can note that between the years 1922 and 1925, treatment of these patients consisted mainly in the administration of a "low fat diet." This diet actually contained a relatively high proportion of carbohydrate but the emphasis was

TABLE II

Course of acute liver insufficiency

	No. of Cases	Deaths	Mortality	
1922-25	10	9	90%	95%
1926-29	14	14	100%	
1930-35	32	20	63%	
Entire Group	56	43	76%	

equally great upon the low level of fat. Glucose was administered by rectum in 3 cases and in very small amounts intravenously in 2 cases. During the next four years hospital orders were changed so that the patients were put on a "high carbohydrate diet" instead of a "low fat diet." It is difficult to determine the exact difference between the two diets but an attempt was made in the second four-year period to give the patient at least between 300 and 400 grams of carbohydrate a day. Four out of 14 cases received some glucose by rectal or subcutaneous routes and 4 had a little intravenous glucose therapy. In one case intravenous glucose was administered over a five day period. In the last six years the dietary treatment of all such cases has been that of a high carbohydrate diet and not infrequently an attempt has been made to give the patient 450 to 500 grams of carbohydrate by mouth. No rectal administration of glucose can be noted but 26 out of 32 cases received intravenous therapy with solutions of glucose ranging from 5 to 25%. In several instances intensive glucose therapy was not possible because of the short duration of the patient's hospital stay before death. There is little doubt that in this particular group of patients much more intensive glucose therapy has been attained in the past six years and it is of interest to note that at the same time there has been a marked decrease in mortality, a drop of about 30%. (Table III).

It is pertinent to inquire at this point whether the group of patients treated in the past six years represented patients who were less seriously ill than those seen in the preceding period. A review of the findings shows that the intensity of the jaundice was no greater in one period than another and an analysis of the figures in Table IV shows that in 33 patients quanti-

TABLE III

Treatment of acute hepatic failure

Time Period	Type of Diet	Rectal or Subpectoral Glucose	Intravenous Glucose	Mortality
1922-25	Low Fat	3	2	90%
1926-29	High Carbohydrate	4	5	100%
1930-35	High Carbohydrate	0	26	63%

tative van den Bergh determinations were made. Of these, 16 reached a jaundice severe enough to give a peak figure of over 20 mgm. per 100 c.c. The mortality of this group was 56%. Seventeen, or an essentially equal number, had a grade of jaundice which carried a quantitative bilirubin of under 20 mgm. per 100 c.c., although the jaundice was still intense and the mortality was 76%. In other words, in these severely sick patients the depth of the jaundice alone obviously is not of critical importance and does not seem to determine the prognosis in any given case. The bromsulphalein test was performed in 24 individuals, or nearly half the series. Eighteen of these had a dye retention of more than 50%, a figure that one could anticipate in view of the extreme degree of jaundice. The mortality in this group was 56%. The remaining 6 had a dye retention of less than 50% but still a relatively high figure, and 5 of these patients died, a mortality of 83%. It would appear therefore that the dye test as well as a determination of the intensity of the jaundice was by itself of little immediate prognostic significance. Inasmuch as the two tests usually sup-

TABLE IV

Relationship of jaundice to prognosis in acute hepatic failure

	Cases	Deaths	Mortality
van den Bergh Over 20 Mgm. Per 100 c.c.	16	9	56%
van den Bergh Under 20 Mgm. Per 100 c.c.	17	13	76%
Dye Retention Over 50%	18	10	56%
Dye Retention Under 50%	6	5	83%

plement each other this is a finding that might have been expected.

It has occasionally been noted by other observers that ascites and general edema may occur in acute liver insufficiency and such a finding is commonly looked for in chronic liver disease. It was somewhat of a surprise, however, to note that in this group of 56

patients at least 25 had demonstrable ascites and 26 had easily demonstrable peripheral edema. The author has commented on the prognostic significance of ascites and peripheral edema in a previous communication (1) and it is certain that they do not occur except in seriously ill patients. That they were as common as is indicated by these statistics has not been pointed out

TABLE V

Relationship between ascites and intravenous glucose therapy

	Deaths	Mortality
Patients with Ascites and I.V. Glucose		
11	7	63%
Patients with Ascites and No I.V. Glucose		
14	13	93%

in the literature. The number of patients showing ascites and edema was no greater in the years before 1930 than after this date and from this criterion alone it would seem that the two groups of patients under discussion presented no great clinical difference from the point of view of severity of the underlying condition. The mortality of all the patients having ascites was 80%, of those showing edema, 80%, and of those showing ascites and edema, 86%. In other words, the mortality of those patients showing such a serious finding was essentially the same as that of the entire group and it can therefore be said that ascites and edema while indicating severe liver insufficiency are not sufficient to be of absolute prognostic importance in any given case.

Of greater interest, however, is the fact that of the 14 patients who had ascites and no intravenous glucose the mortality was 93%. Of those patients receiving intravenous glucose therapy a much lower figure was obtained, namely 63%. This finding would seem to indicate again that the introduction of intensive glucose therapy by the intravenous route had a determining influence upon the favorable outcome in many of the cases. (Table V).

Although the number of cases observed is altogether too small to give more than an indication, it is of interest to note that of the 56 cases 7 showed purpura. All of these patients died.

In view of the high mortality noted among the few patients showing purpura it was thought advisable to see whether bleeding occurred in any appreciable degree from the gastro-intestinal tract. Of 39 patients the survival period was sufficiently long to permit stool examinations. 17 of these showed positive tests for occult blood with gum guaiac. 14 of these patients died, a mortality of 82%, which was that of the entire series and it would seem that there was no intimate connection between the appearance of purpura and the existence of small amounts of bleeding from the digestive tract. The finding of such a high percentage of strongly positive tests for occult blood was also of interest inasmuch as none of these patients had malignancy of the head of the pancreas or the digestive tract and such a finding therefore could not be taken as suggestive of the latter diagnosis. It is also obvious from the above that the presence of occult bleeding from the gastro-intestinal tract is not of absolute prognostic significance.

Study of the various therapeutic measures employed in this group of patients indicates that the main difference to be noted before the year 1930 and after that date lies in the fact that intensive intravenous glucose therapy plus the administration of as large quantities of carbohydrate by mouth as was possible have constituted the only change of importance. That intravenous glucose therapy contributed materially to a reduction in mortality in the condition under discussion would also seem to be a proper deduction. The findings in Table VI certainly suggest that the more intensive the glucose therapy the better the prognosis. It is possible that transfusions during the appropriate periods in the course of individual cases may prove to have been of real importance and observations on a few recent cases would seem to indicate that such a measure might prove of additional importance in critical cases. The use of diuretics or abdominal paracenteses constitute therapeutic measures calculated to give symptomatic relief only. The use of the former, however, is not always associated with satisfactory results and may prove quite disappointing.

In the most seriously ill patients it is obvious from the above data that neither specific clinical findings nor laboratory data can give the information necessary to determine the outcome in a given case. The finding of ascites, edema and purpura is undoubtedly of bad prognostic significance but it is undoubtedly true that such findings do not preclude a favorable outcome. In a previous article (1), the author has stressed the importance of a spontaneous diuresis as one of the most important findings from the point of view of prognosis. That this is true is evidenced from the findings in the cases under discussion. Satisfactory observations of fluid intake and output were made on 41 of 56 cases. In 9 cases, or 22%, a real spontaneous diuresis occurred during treatment. Of the cases in which this was noted all but one recovered.

For purposes of comparison there is also presented an unselected group of 27 cases characterized by acute or subacute liver insufficiency of a somewhat milder degree. In each of the cases the condition had been precipitated by a known liver poison such as arsphena-

TABLE VI

Mortality from hepatic failure in relation to duration of glucose therapy

3 Days or More	9	11	45%
5 Days or More	7	10	41%
10 Days or More	2	7	22%

mine. The chief clinical difference between this group and the preceding one lies in the absence of ascites, edema,* and purpura. The intensity and duration of the jaundice noted in these patients did not differ to any marked degree from those already discussed and certain laboratory tests apparently indicated as great a disturbance of liver function. That the hepatic dis-

* 2 had slight edema.

turbance was not so severe, however, is obvious from the fact that in this particular group there were no deaths. It is of some interest, however, that in two-thirds of these cases intensive glucose treatment by the oral and intravenous routes was carried out. It is of further interest that out of 21 instances where fairly accurate observations were made, a definite spontaneous diuresis was observed in 10 cases, or 48%. As already pointed out, I feel sure that the occurrence of such a diuresis is a sign of the utmost importance as regards immediate prognosis. It is rare indeed to have a patient succumb from acute or subacute liver injury, regardless of the cause, when such a finding has been noted. An excellent example of this fact may

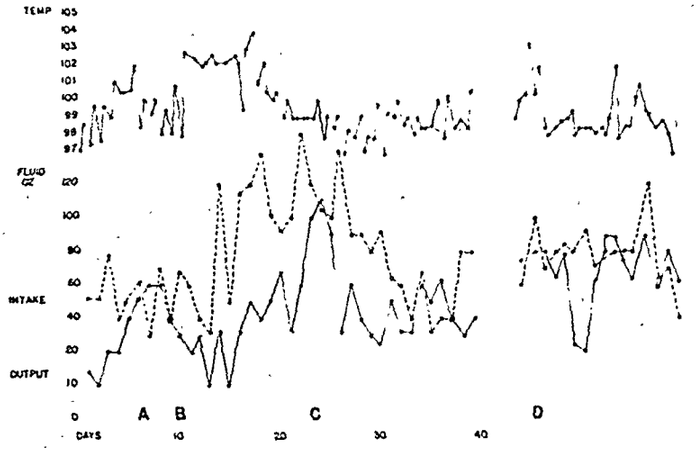

Chart 1. Course of hepatic insufficiency with special reference to urinary output. A. Striking clinical improvement with occurrence of a diuresis. B. Onset of erysipelas. C. Spontaneous diuresis with second period of improvement. D. Bronchopneumonia.

be found in the following case which was followed recently on the medical ward.

The patient, a man of 40 and a confirmed alcoholic, entered the hospital after a prolonged debauch, in obvious liver failure. Physical examination showed a large, obese individual with a coarse tremor such as is seen in delirium tremens. There was moderate icterus of the skin and sclerae, telangiectases on the face and prominent veins on the abdominal wall. The mouth was extremely red and the mucous membranes were dry. The liver was 3 fingers below the costal margin and the spleen was easily palpable. There was a small amount of ascites as evidenced by shifting dullness of both flanks. There was no edema of the extremities. Knee jerks were absent and the patient complained of numbness in the legs and feet suggesting a peripheral neuritis. During the next week his jaundice increased rapidly and the ascites became obvious to the point of distention which interfered with his breathing. There was an associated edema of the extremities.

The intensity of the jaundice waxed and waned throughout the three months in the hospital. The ascites tended to recur periodically after tapping. Laboratory data showed brown stools and a urine which was full of bile until the later weeks of his disease. The red count varied between 3,900,000 and 2,600,000, never going above the first figure in spite of nine transfusions. A quantitative van den Bergh test on admission showed 10 mgm., per 100 c.c., and reached a peak of 21 mgm. 11 days after admission. During the later weeks of the disease the van den Bergh dropped to a level of 3.5 mgm. Serum protein on admission was 6.5% but subsequently dropped to a level of 4.3% and has remained in that vicinity in spite of the numerous transfusions. A brief explanation of this low level can be partly supplied by the failure of the liver to maintain the serum protein and partly by permanent withdrawal of protein from the body associated with 12 abdominal paracenteses.

Intensive glucose therapy was instituted at once. This consisted almost exclusively of intravenous glucose. The patient was extremely difficult to manage until the later weeks of his disease and oral administration was almost impossible. Because of the obvious severity of the condition it was deemed advisable to give 25% glucose and this was carried out in almost daily injections in the past three months. After a stormy course, in which the jaundice gradually increased and ascites and edema, as well as marked mental symptoms, were striking features, there was a period of real improvement. This coincided with a diuresis, noted in the chart at A. Shortly thereafter (see B on Chart) the patient acquired a mild streptococcus infection of his throat. Facial erysipelas followed with increasing general symptoms such as deepening jaundice and delirium and an associated oliguria. At point C on the chart an increased urinary output was noted and again clinical improvement occurred. Two weeks later a further infection (see D on Chart 1) occurred with signs of a bronchopneumonic process at the right base. The patient managed to survive this further insult and again showed a striking increase in urinary output over that observed in the preceding week. From this point on improvement was gradual but continuous and the urinary output was high. It is probably important to point out that transfusions were given at almost ten day intervals, the indications being purpura, a persistent anemia, spontaneous nosebleeds, and a low serum protein. Belly taps were performed for relief of symptoms of distention. This case illustrates well the value of very intensive treatment in the face of the most severe grade of liver failure.

SUMMARY

In summary, we should like to stress the fact that in severe grades of liver insufficiency due to any cause there exist no laboratory or clinical tests that offer absolute prognostic information. Ascites, not previously existing, edema, purpura and a mousy odor to the breath are important clinical evidences of the most severe grades of hepatic failure. Oliguria proceeding to anuria, is of the utmost importance as a bad prognostic sign. Laboratory data confirm but do not accurately measure prognosis. Even in the most severe grades of liver failure as evidenced by the above symptoms, survival with a subsequent high degree of recovery of hepatic function may occur if intensive treatment is instituted. The reduction of the mortality in such cases from over 90% to 60% is apparent and eloquent proof of this statement. Such intensive treatment primarily rests upon adequate glucose intake, preferably by the intravenous route. Such an assumption is borne out by the findings of Althausen (2), Banks (3) and others who have shown in animals that for given amounts of glucose, the administration by the intravenous route is associated with greater glycogen deposition in the liver than when it is administered by mouth. The amount of glucose to be administered depends on the actual need. In the most severe cases

periodic transfusions constitute an added therapeutic measure of great importance. Purpura, anemia, spontaneous hemorrhages, a low serum protein, or failure to improve or glucose alone are the indications for transfusion. The simplest and most valuable prognostic sign indicating a real improvement is the finding of a spontaneous diuresis. This may and frequently does precede any demonstrable change in other clinical or laboratory findings.

DISCUSSION

DR. H. L. BOCKUS (Philadelphia, Pa.): Any contribution to the prognosis and therapy of this type of acute severe liver insufficiency is certainly and decidedly worth while.

I do not think that any of us will disagree with Dr. Jones concerning the serious prognosis in those cases that show an acute edema and acute ascites. I was particularly interested in his comments on purpura. I believe he reported the occurrence of purpura in seven of these acute cases. I have lost two cases, within the past year, who developed a generalized purpura. I would like to ask Dr. Jones whether he has tried Vitamin C intravenously in any of these cases of acute hepatic insufficiency with purpura. I mention that because we have had some rather startling results in Philadelphia in the last few months with Vitamin C in purpura not associated with hepatic insufficiency.

Certainly the development of oliguria and anuria is a very bad prognostic omen. Nor do I think we can differ with Dr. Jones in his mention of the lack of prognostic importance of the serum bilirubin level in jaundice. It could not be expected to be of very much prognostic value.

I am sorry that Dr. Jones did not give us the benefit of his experience, which I am sure has been extensive, with certain other liver function tests in this group of cases from a prognostic standpoint because no one person sees a tremendous number of these cases in any one year. I think if we could group our information on this score it might prove of some value.

In collaboration with Dr. Tumen, I have been going over all of our cases of severe liver disease, not all of them acute, comparing the serum protein level with the various liver function tests. Twelve of the cases in this group were acute hepatocellular jaundice. They were not all of the severe type of insufficiency that Dr. Jones reports. I will give you the benefit of our findings in the serum protein levels in those cases.

The albumin was under 3.6 in seven of the acute cases, and the globulin was over 2.5 in six. The albumin-globulin ratio was less than 1.5 in nine. Three of those patients died, two of them had a serum albumin of less than 2.9 and two of them had an inversion of albumin-globulin ratio. In our experience in the diagnosis of the toxic type of acute liver disease, the galactose retention and possibly a measure of dye retention in conjunction with the serum bilirubin are superior to the serum albumin level. We have had insufficient experience in the acute cases with these particular tests to say anything about them prognostically. I should like to hear of Dr. Jones' experience.

It is interesting to be able to discuss Dr. Jones' paper in conjunction with the first paper by Dr. Wilkinson, a very important contribution to the subject. Dr. Wilkinson mentioned particularly the diminution in the total blood cholesterol, and particularly in the esters in the acute toxic jaundice. A good many European writers have stressed that point. We have been paying particular attention to it for several years. I must say that we have been rather disappointed in our results. It is true that occasionally we found quite a marked lowering in the blood cholesterol in the acute cases. We have seen a great many cases that were definitely hepatocellular in which the cholesterol level was not decreased but increased. I feel that the degrees of concomitant obstruction which is bound to occur in many of these cases must influence the cholesterol level. I wonder what Dr. Jones' experience has been in that regard?

The point of his paper is this, that parenteral glucose should be used in the treatment of acute hepatic insufficiency. I should like to ask Dr. Jones whether he thinks insulin is of any help and also whether he feels that oxygen may not be of value in some.

I should like to stress particularly the necessity for giving the glucose continuously, having lost two patients with acute hepatic insufficiency in hypoglycemia within the past year. One developed an extreme hypoglycemia during the night. We thought we were watching the blood sugar level very carefully. In spite of frequent glucose infusions day and night, the glucose level was below 20 several hours before death. That patient had an acute yellow atrophy of streptococcal etiology associated with purpura developing during the puerperium.

It seems to me that the glucose should be given by the continuous drip method throughout the critical period of the illness. It is interesting, too, that Dr. Garbat's sugar tolerance curves have indicated that the body apparently needs glucose so badly. I was very much interested in his discussion of Dr. Wilkinson's paper because it fits in very nicely with our clinical experience with hypoglycemia in these severe and acute cases of liver insufficiency.

DR. CHESTER JONES (closing the discussion): The point that I was trying to make is what Dr. Bockus has already said, that these patients as a rule have been given up as moribund patients. The surprising thing is that no matter how well they are, no matter how serious the laboratory findings seem to be, a certain portion of them can be pulled through by rather heroic measures. It means, however, that measures have to be started at once and carried through.

These patients represent an excellent example in human beings of what Mann has produced in animals that are hepatectomized; they are getting along practically without a liver. The amazing thing is that one can carry them along by intensive treatment over a period of days or weeks and can rescue a certain number of them.

Purpura, I am sure, is a bad prognostic sign. We haven't tried Vitamin C, nor ascorbic acid in any of these cases. The number of tests that were tried on this particular group of patients under discussion was relatively few and we were trying to get an estimate of the value of two of the simple ones, namely, the quantitative bilirubin and the dye test. The important thing in these cases is to save the veins for intravenous therapy. Therefore, the number of tests that can be done is limited. Otherwise, if one keeps on doing tests one cannot treat the patient very well.

Determination of the serum protein does give an indication of the severity of the hepatic failure but the very fact that there is an edema or an ascites will tell you that the serum protein is abnormally low. One can estimate or guess that beforehand.

The galactose tolerance test has been done on a few cases, and in one or two such cases acute yellow atrophy was proven at autopsy. The glactose tolerance test was normal in both. It gives me little confidence in it as a test for immediate prognosis.

Cholesterol values do vary a great deal clinically. I think that any attempt to gauge the severity of a case and its prognosis by one or two determinations of cholesterol or cholesterol esters is of no greater value than an estimate based on one's own clinical experience in following these patients.

We have used insulin in a few cases. The patient I first referred to has had intensive glucose treatment for three months. The interesting thing is that he has hardly spilled over any sugar in the urine in spite of the very large amounts of glucose administered. At one period of the time in the hospital he was given insulin along with the administration of glucose. It did not materially affect the amount of sugar that spilled over in the urine. We could not see that there was any evidence that insulin really helped in the utilization of glucose.

We have used oxygen in one or two instances. In patients in as serious condition as these, it seems to me it is quite obvious that there may be, among other things, a partial oxygen lack and the use of oxygen may occasionally be of real help.

I also agree with Dr. Bockus that at times it may be wise to insert a cannula into a vein for continuous administration of glucose throughout 24 hours of the day, day in and day out, until one's patient is either better or worse.

Chronic Hepatitis with Jaundice (Biliary Cirrhosis)*

By

JAMES F. WEIR, M.D.

and

ALBERT M. SNELL, M.D.†

ROCHESTER, MINNESOTA

THERE is perhaps no more difficult diagnostic problem than that presented by the patient with jaundice of long standing, and certainly there is no condition in which efforts at treatment are less satisfactory. These patients often present the diagnostic criteria of what has been termed "biliary cirrhosis," that is, they have suffered for months or years from jaundice, intermittent pain over the region of the liver, pruritus, and digestive disturbances. On examination a symmetrically enlarged and firm liver, a splenic tumor, and factitious dermatitis from scratching are found; the biliary passages are patent, and the urine is stained with bile. From the standpoint of clinical symptoms and functional disturbances these patients present most of the characteristics of a chronic, and primarily intrahepatic, type of jaundice. Such cases of chronic jaundice are ordinarily grouped in the convenient catch-basket of "biliary cirrhosis," and thereafter the patients are treated only perfunctorily and with failure acknowledged in advance. One may borrow Corvisart's statement in regard to heart disease, when he criticized those who "looked on attempts at an exact diagnosis (in such conditions) as useless, because those diseases are incurable."

The term "biliary" in hypertrophic biliary cirrhosis implies that the noxious agent enters through the biliary ducts. This may be true of the obstructive cirrhosis and possibly in a small group of cases in which the condition is infectious in origin. However, in a large number of cases of chronic jaundice, as will be shown later, there is no evidence whatever of any obstruction or infection of the biliary ducts. Hanot's name has been associated with this condition. His thesis, published in 1875, was entitled, "Hypertrophic cirrhosis of the liver with jaundice." At this time there was still a great deal of argument as to whether or not this condition was a separate entity. Grossly, the essential feature was an enlarged liver, as contrasted with the small liver established by Laennec as characteristic of atrophic cirrhosis. Microscopically, the connective tissue infiltrated the lobules, as well as surrounded them, as it did in the atrophic form. German authors, however, continued to deny the existence of hypertrophic cirrhosis as a separate entity. There are today many authors who deny that hypertrophic biliary cirrhosis exists as a separate entity. Dr. W. J. Mayo pointed out the frequency with which chronic hemolytic jaundice and splenic anemia were confused with this condition, and Bloomfield, for example, omitted it from his classification of hepatic diseases.

Perhaps the term "biliary" should be dropped from descriptive terminology, unless it be restricted to cases of parenchymatous hepatic disease to indicate that chronic jaundice is a particular feature. This is in line with the idea of Rolleston and McNee, who expressed the opinion that there is a distinction between hypertrophic biliary cirrhosis and atrophic cirrhosis, and that this distinction is chiefly in the presence, in the former, of a chronic persistent jaundice. However, as they also pointed out, both conditions may affect the same patient, and the atrophic form may show many other features of the hypertrophic form, such as enlargement of the liver and spleen. In other words, the two conditions may not be distinct.

CLASSIFICATION

In a clinical consideration of chronic jaundice, it is first necessary to establish a tentative nomenclature and an arbitrary classification. We use the term "chronic hepatitis" only in its clinical sense, except in a few instances when referring to pathologic lesions; "cirrhosis" is used as a descriptive term for a more advanced process characterized by nodular hyperplasia, and "chronic atrophy" is used to describe a contracted and atrophic liver with degeneration of the hepatic parenchyma. The classification to follow is purely tentative and is intended primarily to avoid confusion; it is open to the objection of being based in part on clinical data and in part on pathologic findings. Chronic hepatitis with jaundice, therefore, can be classified as follows: (1) chronic biliary obstruction with resulting cholangeitis and hepatitis; (2) chronic infectious and toxic forms of hepatitis, including toxic cirrhosis;

*Delivered at the Thirty-ninth Annual Session of the American Gastroenterological Association, Atlantic City, N. J., May 4-5, 1936.

†Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

Approved by the Committee on Publications.

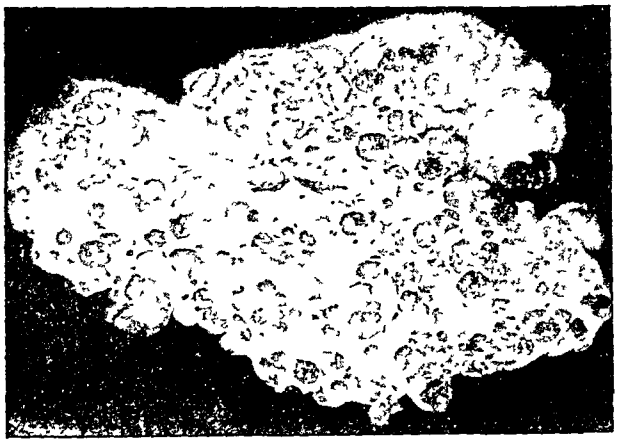

Fig. 1. Liver of a girl aged eleven years. Details are given in the report of Case 2. Liver weighed 711 gm. Dense fibrous tissue surrounding nodules of greenish or reddish tan color.

(3) chronic atrophy of the liver; (4) parasitic hepatitis; and (5) hepatitis secondary to familial bilirubinemia (constitutional hepatic dysfunction). This classification is by no means complete or inclusive, but it is at least possible to demonstrate examples of each of these types in a mixed group of cases of hepatitis with chronic jaundice and enlarged livers, as we shall show. For obvious reasons, we have omitted the pigmentary and syphilitic forms of hepatitis from consideration.

CHRONIC BILIARY OBSTRUCTION

The effects of calculous, cicatricial, and neoplastic obstruction on the structure and functions of the liver need no detailed consideration. It suffices to say that a considerable number of patients, who are, in reality, suffering from biliary obstruction, present themselves with a clinical picture that is difficult to distinguish from that produced by the infectious forms of hepatitis. The gross and microscopic appearance of the liver under these conditions is indistinguishable from that seen in supposedly primary types of cirrhosis, except for evidence of dilatation of the biliary ducts which indicates obstruction. Ductal and periductal inflammatory reaction from ascending infection may occasionally be present, but this cannot be demonstrated pathologically in many cases in which it is clinically suspected. Disorganization of the hepatic structure and portal obstruction may be sufficient to produce ascites, edema, and macrocytic anemia, which also are found in atrophic cirrhosis. The complete picture can be duplicated experimentally by ligation of the common bile duct of animals. In cases of obstructive cirrhosis, operation may be curative, even if the pathologic process is far advanced.

Following satisfactory removal of biliary obstruction, jaundice usually disappears, even if it has been present for a long time and extensive hepatic changes have taken place, however, a latent icterus and minor degrees of retention of bromsulphalein may persist for months or years after operation. Even in cases in which the liver has been damaged sufficiently to produce portal obstruction with ascites, patients may make a surprising recovery. An occasional case is seen in which the hepatic lesion progresses after operation. If obstruction cannot be relieved satisfactorily, as in some cases of extensive cicatricial contraction of the common bile duct, chronic jaundice may persist with associated ascending cholangeitis and hepatic enlargement and the terminal features will be those of ascending biliary infection, hepatic insufficiency, and cholemic bleeding. The obstructive cirrhosis that is secondary to congenital obliteration of the biliary ducts, choledochus cysts, and benign tumors of the biliary ducts may also be mentioned under this heading; because of the rarity of this type of cirrhosis no clinical description will be attempted.

There are certain rare cases in which there is a true cholangeitis and pericholangeitis, with a secondary hepatitis. The best clinical examples are seen following cholecystogastrostomy; diffuse hepatitis following this operation is by no means as common, however, as experimental studies would lead one to suspect. After cholecystogastrostomy, or after transplantation of the common bile duct into the intestine of the experimental animal, an ascending cholangeitis develops. Later, there is proliferation of connective tissue, and an inflammatory reaction with profuse lymphocytic infiltration about the biliary ducts. Miliary abscesses and a diffuse suppurative process are the usual terminal developments.

Diagnosis of these so-called obstructive forms of chronic hepatitis depends principally on suspicion, on signs of partial or intermittent biliary obstruction, and on the fact that hepatic functional tests frequently show more evidence of parenchymal hepatic damage than one encounters in the case in which nonobstructive hepatitis is of the same duration. Stone and stricture are the principal causes of chronic painless jaundice of this type; a neoplasm usually causes death long before the stage of cirrhosis is reached.

TOXIC AND INFECTIOUS FORMS OF CHRONIC HEPATITIS

When one eliminates patients who have obstructive forms of cirrhosis from a group of patients who have chronic jaundice, there remains a large and heterogeneous collection of patients whose hepatitis is believed to rest on a toxic or infectious basis. Just how the hypothetical toxins and bacteria reach and act on

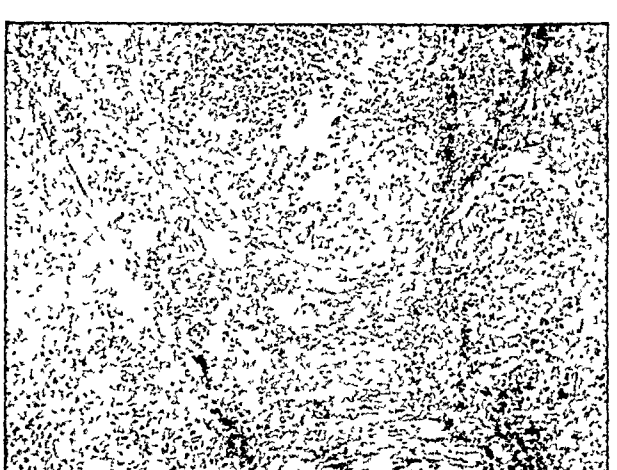

Fig. 2. Same case as that represented in Fig. 1. Extreme increase of connective tissue with collections of lymphocytes and adenomatous proliferation of liver cells. Complete disarrangement of normal structure.

Fig. 3. Liver; A, gross and B, microscopic. The patient was a woman aged thirty years. Jaundiced for two years. Liver enlarged. Serum bilirubin 12.5 mg. per 100 c.c. Death from intercurrent infection. Liver weighed 2682 gm. and was large and greenish, with finely granular surface and indistinct marking. Markedly swollen liver cells containing bile pigment. Slight increase in connective tissue which contained collections of lymphocytes and few polymorphonuclear leukocytes. Masses of bile in bile ducts.

the liver is largely a matter of conjecture. In the majority of cases the noxious agent probably reaches the liver by the blood stream. One school of thought holds that the effect is primarily on the supporting structure of the liver, which leads to an active proliferation of the connective tissue, a chronic interstitial hepatitis, which eventually affects the cells of the hepatic lobule. Epplen's excellent article pointed out the unlikeliness of this view. Another school holds that the effect of the toxin is primarily on the hepatic parenchymal cell, which undergoes degeneration or necrosis; acute yellow atrophy is a typical severe form. It is presumed that such toxins may be weak or strong, and may produce slight or extensive degeneration, which may vary from patchy to almost universal distribution. There may be single, acute episodes of toxic damage, which may recur frequently or may act for a prolonged period. As a result of the necrosis of hepatic cells thus produced, the lobule degenerates; if the subject survives, regeneration of the hepatic cells occurs. These changes are illustrated in livers affected by the toxic cirrhosis of Mallory, or "healed yellow atrophy" a term suggested by Wilson and Goodpasture. Bell said that it is very difficult, if not impossible, to distinguish this state from the ordinary atrophic cirrhosis. Many feel that this process of destruction and regeneration is the essential basis of all forms of parenchymal hepatic disease and that the different pathologic pictures are different stages or manifestations of the same process. Studies on experimentally produced hepatic lesions furnish strong support for this contention. Rolleston and McNee adhere to a course midway between the two schools of thought which have been mentioned; they maintained that the toxins also affect the supporting structure of the lobules, and produce active proliferation of the connective tissue as well as necrosis of the hepatic cells. The general trend of opinion, however, is toward the theory that the hepatic parenchymal cell is the primary site of injury.

In an endeavor to learn more of the clinical course and etiologic factors in the toxic and infectious types of chronic hepatitis and chronic atrophy, a series of fifty-three cases, in which chronic jaundice was not attributable to obstruction of the biliary passages, has been reviewed. There were twenty-three males and thirty females in the group of patients and their ages varied from eleven to sixty-seven years. In this group as a whole, the duration of jaundice varied from three months to nineteen years while in thirty-eight cases the duration varied from six months to five years. The degree of jaundice present was, as a rule, relatively slight, but an occasional case was encountered in which deep jaundice was present. In three cases in which there was deep jaundice, the process was relatively acute, but all three patients eventually recovered and are well some years later. In one case, intense icterus was a terminal development (icterus gravis); in another case it was of relatively long duration, and the patient died in one year from the beginning of the jaundice.

Pruritus, which was a common feature, was present in a high percentage of cases. It was absent in nine cases but in many cases it was the most prominent symptom and caused the most distress. Curiously enough, these patients presented relatively mild icterus, although in two cases in which the condition had been present for three and ten years respectively, there has been gradually deepening jaundice.

In a considerable number of cases, pruritus was the predominating symptom, with later development of melanosis, jaundice, and enlargement of the liver and spleen. Eight such cases were encountered in the group reviewed. Pruritus of three to five years' duration was present in five cases, it had been present for one year in one case, and for ten to twelve years in two cases.

In thirty-six cases, the liver showed marked enlargement which frequently extended to the region of the umbilicus. The liver usually was firm, smooth, and not definitely tender. The spleen was palpably enlarged in thirty-one cases, and in nine cases the enlargement was considerable. Ascites was a prominent feature in eight cases, although small amounts of free fluid were demonstrated in a number of others. In six of the eight cases, the ascites had been present for from three months to three years. All but one of the patients in these cases are known to be dead, and the sole survivor has required paracentesis regularly. In one case the

Fig. 4. Liver; A, gross and B, microscopic. The patient was a woman aged sixty-two years. Biliary colic four years before examination. Indigestion thereafter. Painless jaundice four months. Death from hepatic insufficiency. Liver weighed 1218 gm. Moderate increase of connective tissue with atrophy of parenchyma. Connective tissue increased, with collections of lymphocytes and bile ducts. Atrophy and fatty changes of liver cells.

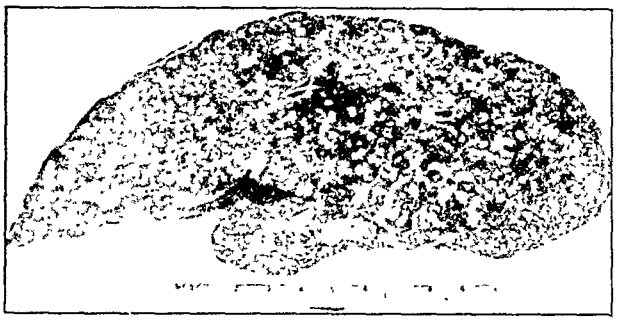

Fig. 5. Liver of a woman aged fifty-nine years. Jaundiced for five years. Ascites for six months. Serum bilirubin 5.8 mg. Death from hepatic insufficiency. Liver weighed 815 gm. and was moderately contracted and nodular with lighter areas of necrosis and darker areas of adenomatous proliferation.

ascites was present for six years before death. In one case the ascites, which had been present for four weeks, disappeared after the use of diuretics but recurred two or three times later. The patient in this case is now well. Of seven patients who had slight ascites, five are dead and the other two are well; one of the latter had been jaundiced for more than a year.

Melanosis was particularly prominent among the group who had pruritus; one patient presented almost a Negroid appearance. Osler mentioned a similar case in which the skin was "very bronzed, almost as deeply as in Addison's disease." In the whole group, melanoderma was present in eleven cases. In such cases, it is necessary to differentiate hemochromatosis, the pigmentation of chronic arsenical poisoning, and a simple melanosis, a point which is best settled by biopsy. Such a biopsy was obtained in nine of these cases; in two cases arsenic was demonstrated, and iron was present in one case. The remaining cases showed only excessive deposits of melanin.

Mild anemia frequently was present and macrocytosis was noted in twelve of nineteen cases in which blood smears were examined. Significant hemorrhage occurred in eleven cases; this apparently resulted from ruptured varices in six cases; in other cases a generalized hemorrhagic tendency was present.

Exploration of the abdomen was performed in twenty-seven cases; splenectomy was done in one case, omentopexy was performed in three cases, and exploration alone or with drainage of the gall bladder or common bile duct or with cholecystogastrostomy, was performed in the remaining twenty-three cases. In only one case of this group was any evidence of obstruction found in the common bile duct. The surgical procedures appeared to make little difference in the progress of the disease in those cases in which the patients survived. There were four postoperative deaths.

At operation the liver presented varying appearances. In the majority of cases it was much enlarged. In a few cases in which the condition was advanced, it was smaller than normal and presented a hobnail appearance. The consistency of the enlarged livers varied from normal to sclerotic; some were smooth, while others were granular or even nodular. In some cases the liver grossly appeared fairly normal, except for the increase in size. Occasionally it was described as appearing congested. The spleen frequently was found to be enlarged; in some cases the spleen was five times its normal size. The common bile duct usually showed little evidence of disease. Occasionally some enlargement of lymph nodes was found in the vicinity of the common bile duct. Biopsy of the liver was performed in five cases.

Twenty-four of the entire group are known to be dead, but more than 10 per cent of the original group are apparently well. The remaining patients continue to suffer from the disease; in some cases the disease has been progressive, but improvement has occurred in a few cases. The prognosis in the majority of cases does not appear to be encouraging.

In a search for etiologic factors in these cases, one meets great difficulties. Cinchophen was an apparent factor in one case. Alcohol possibly played a role in three cases; arsephenamine, in one; inorganic arsenic, in one; arsephenamine and alcohol, in one; arsenic and cholecystic disease, in two; and a combination of syphilis, arsphenamine, and cholecystitis, in one. One may take the following views as to the relationship of these hepatotoxic factors to the disease process; (1) that they are etiologic factors wholly or in part; (2) that they are not of etiologic importance but merely coincident findings; and (3) that the cholecystic disease is in some instances the result of the hepatic disease. There seems little doubt that inorganic arsenic, arsphenamine, and cinochophen are definite hepatic toxins. In three cases inorganic arsenic was a probable etiologic factor; at least, in these cases, chronic jaundice and hepatomegaly were associated with definite signs and symptoms of chronic inorganic arsenic poisoning. The case against alcohol is by no means conclusive. Experimental cirrhosis has not been produced with alcohol, yet fatty changes occur and render the liver more susceptible to other toxins. Clinically, alcohol appears to act in combination with other hepatotoxins.

Three cases were encountered in which some toxin incidental to pregnancy appeared to be a factor. In two of these, pruritus began in the course of pregnancy; in another, the patient had noted slight scleral icterus for one year prior to pregnancy. One of these patients died six months after delivery, as a result of continued jaundice and ascites; another patient who lived twelve years, suffered chiefly from pruritus and finally died of a gastro-intestinal hemorrhage. The

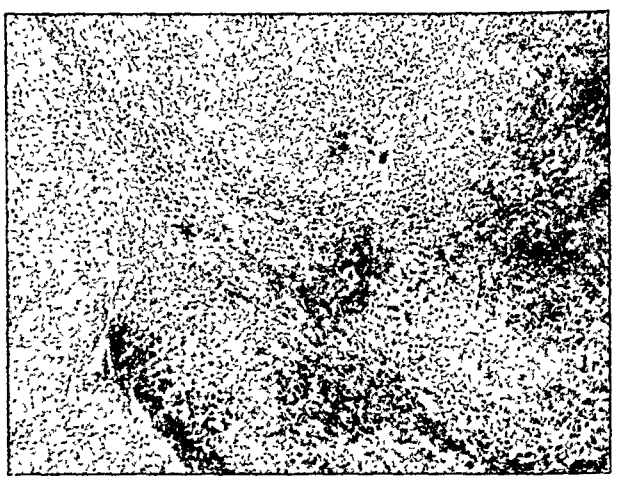

Fig. 6 Same case as that represented in Fig. 5. Increase of connective tissue trabeculae, bile thrombi, and areas of necrosis.

third patient continued to have symptoms for one year and then recovered. Ten years after recovery, she was enjoying excellent health. We have no records of necropsy in the two cases in which death occurred but the chronic nature of the disease assures a more extensive and chronic pathologic change than that seen in the usual toxemias of pregnancy.

Hepatic degeneration also occurs occasionally in the course of exophthalmic goiter, although in this series no such association was encountered. Neither did malaria and typhoid fever appear to be etiologic agents in any case in this series. No cases were encountered in which the disease began as an epidemic catarrhal jaundice, such as it did in those cases reported by Jones. There were no instances of splenic anemia in this series. One patient had an associated diabetes but there were no signs of hemochromatosis; in another case, in which there was cutaneous pigmentation, biopsy revealed iron in the skin.

Cases in which a definite infectious element seemed to play a part were of great interest. These may be considered under three groups: (1) those in which the disease involved the biliary tract primarily, with associated cholecystitis, cholelithiasis, and cholangeitis; (2) those in which there were associated systemic infections, and (3) those in which infectious processes were confined to the intestinal tract.

The first group warrants particular consideration, since cholecystectomy is frequently advised and carried out in such cases, with results that are usually unsatisfactory and not infrequently tragic.

There is much to suggest that long-standing biliary infection leads to serious hepatic damage. However, the hepatitis or cirrhosis may not be the result of biliary infection but may be primary, and the involvement of the gall bladder may be secondary. This was probably true in a number of cases in this series. It has been pointed out that clinically suspected cholangeitis cannot often be demonstrated pathologically in disease of the biliary tract, and it also must be acknowledged that the hepatitis described in association with cholecystic disease is often a purely local and superficial lesion which produces little effect on hepatic structure or function.

The importance of systemic infectious diseases, which was mentioned previously, has probably been underestimated. As pathologists have been pointing out for years, any severe infection leaves its mark on the liver; it is not uncommon to note extensive fatty change, focal necrosis, and other evidences of injury to the parenchyma. Whether such lesions lay the groundwork for the chronic hepatitis of later years is only a matter for conjecture; clinically, it does appear that infectious disease may initiate serious hepatic damage or provoke an exacerbation of a preëxisting hepatitis. In one case in the group studied, the hepatic disease apparently resulted from a severe systemic infection.

Chronic hepatitis may be associated with gastrointestinal disease of an infectious nature. We have recently observed two remarkable cases in which long-standing chronic hepatitis was associated with chronic ulcerative colitis; one of the patients in these cases had intractable diarrhea and anemia long before any signs of hepatic disease were present; in the second case, the time relations were less definite, but the colitis was clinically of some etiologic importance. In Case 1 it is possible that the achlorhydria permitted extension of the fecal flora as high as the duodenum, and permitted the occurrence of an ascending infection of the biliary tract similar to that which Hurst claims to be the most frequent mechanism of cholecystic disease.

Case 1. A man, aged thirty-one years, came under observation in March, 1936. Twelve years before he came to the clinic he had suffered from attacks of bloody diarrhea, which had lasted one to two weeks and had occurred two to three weeks apart. These attacks had occurred for one year; since then his bowels had moved five to six times daily, but with little distress or annoyance. Ten years before he came to the clinic, he had become pale. For five years he had noted a yellowish color of the skin, especially during summer months. There had been mild associated pruritus, which had persisted. Three years before he came under our observation, his condition had become so disturbing that he had consulted a physician. A marked anemia had been found. The value for the hemoglobin had been 40 per cent and the erythrocytes had numbered 1,500,000 per cubic millimeter of blood. Iron and liver had been prescribed, with marked benefit. In August, 1935, definite jaundice had been noted. He had not lost any weight and had not suffered any distress.

Examination at the clinic revealed that he was moderately jaundiced. The liver and spleen were slightly enlarged. The value for the hemoglobin was 15.9 gm. per 100 c.c. of blood and erythrocytes numbered 4,400,000 per cubic millimeter of blood. A fairly marked macrocytosis was present. Gastric anacidity was demonstrated. Roentgenologic examination of the esophagus, stomach, and small intestine revealed no abnormality, but roentgenologic examination disclosed slight mucosal changes throughout the colon. Proctoscopic examination revealed a granular mucosa that bled readily. The value for the serum bilirubin was 12.0 mg. per 100 c.c. The retention of bromsulphalein was grade 4. The result of the galactose tolerance test was normal. The excretion of hippuric acid was 4.86 gm. The value for the cholesterol was 463 mg. per 100 c.c. of plasma, and that for the cholesterol esters was 477 gm. per 100 c.c. of plasma. Bargen's diplostreptococcus was cultured from the stools, but could not be found in the duodenal contents. However, the latter contained Streptococcus faecalis. The diagnosis was chronic ulcerative colitis and chronic hepatitis with icterus.

After the cases in which the disease was of known toxic or infectious origin are excluded, there remains a group of equal or greater size, in which it was not possible to arrive at any definite conclusion as to the etiology. Indeed, Osler said that the absence of an etiologic factor was a remarkable feature of the disease. This is comparable with the situation in diseases of the kidney. There is considerable evidence to suggest that some metabolic disturbance may occur primarily, and produce fatty or other degenerative changes which render the liver susceptible to the effects of toxins or infections. As these cases are more thoroughly studied it may be possible to determine some definite etiology. Rolleston and McNee said that in some of these cases the disease may be the result of an ascending infection, but that in the majority of cases, like cases of scarletiniform nephritis, the condition is the result of hemic infection or intoxication of a chronic nature. Some of the cases undoubtedly belong to the group designated "toxic cirrhosis," and others are cases of chronic atrophy.

To summarize the etiologic findings in the group of cases in which chronic hepatitis is probably toxic or infectious in nature, one may say: (1) that there are cases in which a history of some chemical poisoning is obtainable, and in which the clinical picture in a

general way resembles that of the condition that has been designated as "toxic cirrhosis"; (2) that in other cases the disease appears to be of an infectious nature, the infection arising in the biliary or gastro-intestinal tract, or as a systemic infectious disease; and (3) that in a large group of cases the etiology is unknown.

PARASITIC HEPATITIS

The parasitic form of hepatitis with jaundice may be dismissed with brief comment. A diffuse amebic hepatitis is occasionally seen, but it is rarely characterized by jaundice or the development of cirrhosis. In the temperate climates, parasitic obstruction of the biliary ducts is chiefly of academic interest. Ascaris may invade the extrahepatic biliary passages and thus produce an obstructive type of cirrhosis. Clonorchiasis is responsible for diffuse hepatic damage, but this feature of the disease is overshadowed by the other manifestations. The diagnosis of these latter conditions is seldom made except at operation or necropsy.

CHRONIC ATROPHY

Occasionally, a patient is encountered who has slight but very chronic jaundice without other striking clinical features, except for hepatic enlargement. Such individuals may remain in reasonable health and the disease may show no particular progression for a long time (five to seven years in two of our cases); then, ascites, a hemorrhagic tendency, and hepatic coma may develop suddenly. The clinical course often resembles that of the toxic or infectious form of chronic hepatitis and the etiology may or may not be known. Clinically, the condition usually is diagnosed as biliary cirrhosis. The interesting feature of two of our cases was the pathologic evidence of a very chronic form of hepatic atrophy, which must have existed long before signs of hepatic insufficiency developed.

Case 2. A girl, aged eleven years, had suffered from fluctuating and entirely painless jaundice for seven years before she came to the clinic. For two and a half years a gradually increasing distention of the abdomen had been noted, and for a few months before she came under observation, impaired appetite, weakness, languor, and drowsiness had been conspicuous. Frequent epistaxis had been a late development. A diagnosis of Hanot's cirrhosis had been made by her family physician.

Physical examination at the clinic revealed that the patient was well developed and well nourished; she weighed 147 pounds (66.7 kg.) and her height was 64 inches (162.6 cm.). Moderate icterus and ascites were present; the liver was not palpable, but the spleen was easily felt. There was a slight edema of the ankles and clubbing of the fingers. The value for the serum bilirubin was 10 mg. per 100 c.c. and the van den Bergh reaction was direct. Retention of bromsulphalein was grade 4. The value for the hemoglobin was 11.5 gm. per 100 c.c. of blood and the erythrocytes numbered 4,150,000 per cubic millimeter of blood. A respiratory infection was followed by profuse bleeding from the mucous membranes, and by coma and death. Necropsy revealed a marked atrophy of the liver with very extensive adenomatous regeneration (Figs. 1 and 2).

It is well established that chronic atrophy and portal cirrhosis are really identical conditions. The curious feature of the cases which have been cited was the long continued and definite jaundice. The ascites and symptoms of hepatic insufficiency indicated an advanced lesion; this was confirmed pathologically. Numerous other cases of similar type were encountered in the group studied. The liver was not always enlarged but chronic jaundice was always present. Such cases as these suggest that the pathologic process is similar, whether jaundice is present or not, and that chronic hepatitis, with or without jaundice, in the final stages may progress to chronic atrophy. Deep icterus is seldom seen as a prominent symptom in the usual form of atrophic cirrhosis, except as Rolleston's "signal icterus" or in the terminal stages, although it may appear for brief periods in the course of the disease. Such episodes probably represent an acute process of hepatic degeneration and are often followed by anemia, edema, ascites, and other signs of increasing damage to the liver.

FAMILIAL HYPERBILIRUBINEMIA (CONSTITUTIONAL HEPATIC DYSFUNCTION)

For some years we have been interested in following the course of a group of individuals who have slight visible jaundice, an indirect van den Bergh reaction, and a slight but persistent hyperbilirubinemia, without definite evidences of hepatic disease or blood dyscrasia. For want of a better term, these conditions have been characterized as "constitutional hepatic dysfunction," the principal physiologic defect being a high hepatic threshold for bilirubin. That the hyperbilirubinemia is the result of hepatic dysfunction and not caused by an overproduction of bilirubin seems to have been well established by the work of Rozendaal, Comfort and Snell. As we will show later, this is the principal, if not the only, demonstrable functional disturbance in the presence of the milder degrees of chronic hepatitis. It, therefore, has not been surprising to find that in some of these cases in which the degree of hyperbilirubinemia has been minimal, definite signs of a progressive hepatic lesion and of disease of the biliary tract have developed with the passage of time.

In one case in which the condition had been present for a long time, mild jaundice was encountered; the value for the serum bilirubin varied from 3.3 to 6.7 mg. per 100 c.c. The van den Bergh reaction was indirect and the excretion of bromsulphalein was normal. An enlarged spleen was removed because of the possibility of an atypical hemolytic icterus; this did not produce any change in the patient's condition or in the degree of bilirubienemia.

THE CLINICAL COURSE OF CHRONIC HEPATITIS

In any group of cases of chronic nonobstructive jaundice, various stages of the disease may be present. In the majority of cases the condition is slowly progressive with gradually increasing icterus. In other cases the condition may progress more rapidly, with or without significant decrease in the size of the liver. If the patient survives long enough, chronic atrophy of the liver usually results. This is the usual course, but is more particularly true of the cases in which there are mild degrees of icterus. These cases, clinically and pathologically, resemble the usual case of portal or atrophic cirrhosis, except for the persistent jaundice. Improvement and apparently recovery occurred in 10 per cent of the cases in this series. In two cases in which the value for the serum bilirubin averaged 10 to 20 mg. per 100 c.c. for some months, recovery eventually occurred. In these cases the pathologic condition, perhaps, was subacute and the disappearance of the toxin probably permitted regeneration to occur.

Although symptoms are absent in some of these cases for a number of years, symptoms of chronic atrophy eventually develop. Long-continued jaundice which increases in degree and episodes of more intense jaundice or evidences of portal obstruction indicate a progressive lesion. In cases in which the disease is more chronic, ascites, particularly, indicates extensive disorganization of hepatic structure. However, in reviewing this group of cases we have been impressed by the fact that the patients live for a remarkably long time, many of them remained in an apparent stationary condition, clinically, for years. Thus, in one case, jaundice was present for ten years before the development of ascites, which occurred six years before examination. In other cases, progression may be extremely slow and pruritus may be the most significant symptom.

Case 3. A man, aged forty-one years, was seen at the clinic in 1925, 1931 and 1934. In 1921 he had had a two weeks' illness which had been characterized by jaundice. When he first came to the clinic he complained of pruritus, which had been present for nine months; he had lost 18 pounds (8.2 kg.). Examination at the clinic revealed a factitious dermatitis. The liver and spleen were only slightly enlarged. The value for the serum bilirubin was 2.2 mg. per 100 c.c., but the van den Bergh reaction was direct. The bromsulphalein test for liver function revealed a retention, grade 3. In 1931, his symptoms were improved. There was, however, some melanoderma and distinct jaundice; the value for the serum bilirubin was 5 mg. per 100 c.c. In 1934, his condition was somewhat worse than it had been previously; he had had attacks of epigastric pain with rigidity and tenderness. He had lost 10 pounds (4.5 kg.) and there was slight edema of the ankles. The liver and spleen were readily palpable. The value for the serum bilirubin was 10.7 mg. per 100 c.c. and macrocytic anemia was present.

The late complications arising in the course of chronic hepatitis with icterus are similar to those occurring in all chronic hepatic disease. These include evidences of portal obstruction, such as esophageal varices with or without rupture and hemorrhage, ascites, acute hepatic degeneration, icterus gravis, and hepatic insufficiency. The latter may be manifested by drowsiness, stupor, coma, convulsions, various reflex changes, hemorrhagic manifestations, evidences of renal insufficiency, and generalized edema.

TESTS FOR LIVER FUNCTION IN CHRONIC HEPATITIS WITH JAUNDICE

It must be admitted that tests for liver function are of limited value in cases of chronic icterus. The van den Bergh reaction is almost invariably direct, a fact which may be of importance in subclinical degrees of icterus. The quantitative determination of the serum bilirubin by this method gives further information. The value for the serum bilirubin was less than 5 mg. per 100 c.c. in twenty-three cases, 5 to 10 mg., in eighteen cases; 10 to 15 mg., in seven cases, and more than 15 mg., in five cases. In this series, the degree of retention of bromsulphalein was determined in thirty-seven cases. In all but four cases it was grade 3 to 4. In three of these four there was no retention after the patient had recovered from the hepatic injury. In the fourth case a very mild icterus was present and the van den Bergh reaction was indirect. Marked retention is to be expected in cases in which visible jaundice is present. There may be slight or moderate retention of dye after the value for the serum bilirubin has returned to normal in the process of recovery; at the onset of hepatic disease, the reverse situation usually obtains. Greene, McVicar, Snell and Rowntree have considered some of these tests in a previous article.

There is seldom any disturbance of the functions of the liver in regard to the metabolism of protein, carbohydrate, and fat, unless there be some complicating lesion such as diabetes mellitus or an episode of acute atrophy of the liver. Galactose tolerance tests were done on twenty occasions in sixteen cases, and in all but two instances normal results were obtained. In one of these cases, fatal hepatic insufficiency followed cholecystostomy; in the other case the patient survived exploratory laparotomy without difficulty.

The hippuric acid test (Quick) was done in seven cases; in only one case was it strongly positive and the

patient in this case died soon afterward. Death also occurred in two of the cases in which the synthesis of hippuric acid was normal.

Macrocytic anemia is a common finding and may be the first sign of failing hepatic function. A determination of the total serum proteins was done and found to be normal in thirteen cases. However, reversal in the albumin-globulin ratio was found in seven of the thirteen cases; a definite decrease in the albumin content was noted in all of these cases.

The Takata-Ara test was positive in three of the four cases in which it was done. Its significance has not been fully determined and little importance can be attached to this finding at present. A summary of functional tests in a small group of these cases is shown in Table I.

Functional tests as a rule are of more clinical importance in the study of the obstructive types of biliary cirrhosis than they are in the study of other types of biliary cirrhosis. In the obstructive type of biliary cirrhosis much information may be obtained from estimations of serum bilirubin. In the more chronic types of biliary cirrhosis, the values for the serum bilirubin usually vary from 3 to 5 mg. per 100 c.c. In the presence of cholangeitis, values of 8 to 15 mg. per 100 c.c. are common; the higher values usually are indicative of hepatic injury of considerable degree. Retention of dye which is greater than that anticipated as a result of the existing degree of bilirubinemia may occasionally be found. In cases of obstructive types of hepatitis in which there are acute degenerative hepatic lesions, the galactose tolerance and hippuric acid tests may often be positive, and in cases in which the disease is very chronic, some lowering of the value for the proteins in the plasma, and reversal of the albumin-globulin ratio are not uncommon. Macrocytic anemia is common. A summary of the functional findings in a small group of cases is shown in Table II.

To summarize the findings of functional studies in chronic hepatitis, it can be said that the principal disturbances have to do with the excretion of bile pigment, and as a corollary of this, the disturbances of excretion of various dyes. Increasing bilirubinemia indicates a progressive lesion. Other functional tests may be of value in determining the severity of acute degenerative episodes. These tests are of some practical importance, especially in the obstructive types of hepatitis, in estimating the chances for the patient to survive contemplated operation.

PATHOLOGY

Specimens have been obtained from the livers, at operation, in five cases. These are, of course, open to the general objection that they do not necessarily represent a true picture of the general condition of the liver. Furthermore, localized milder changes may be a more or less normal occurrence. In one case in which jaundice had been present for six months, some fatty degeneration, a few collections of lymphocytes between the lobules, and a slight staining of the cells with bile were the only findings. In another case in which symptoms had been present for four years, there were similar changes although they were slightly more prominent. In the other three cases there were similar changes in addition to slight to moderate proliferation of connective tissue. In no case was there evidence of changes in or about the biliary ducts.

Necropsy was performed in nine cases. In one case in which the condition had been present for six months, a subacute yellow atrophy was found. In another case in which symptoms had been present for two years and in which the patient died of an intercurrent infection, a chronic hepatitis was found. This was the only case in which the liver weighed more than normal. In all the other cases there was a chronic atrophy of varying degree. The degree of regeneration varied considerably as did the amount of proliferation of connective tissue; in no case was there evidence of involvement of the biliary ducts. Sections are shown in Figures 1 to 6. It is to be particularly noted that specimens obtained at operation represent early changes, whereas, specimens obtained at necropsy represent a terminal stage of the disease. In other words, the pathologic picture depends on the stage at which the observation is made. These findings, especially notable in the cases of chronic atrophy, are similar to those found in cases in which jaundice is not a significant feature, just as jaundice may be absent in the cases of acute yellow atrophy. It is our impression that jaundice is not a necessary accompaniment of hepatic disease, although its presence is a striking clinical symptom and at once directs attention to the

liver. Why jaundice is present in some cases and absent in others is at present an enigma.

TREATMENT

Medical treatment of these patients is not very satisfactory. If some etiologic factor, such as chemical poisons, hyperthyroidism, or associated syphilis, can be eliminated, the disease can at times be arrested and recovery takes place. Any definite foci of infection should probably be removed. This perhaps is one important reason for a surgical treatment of associated disease of the gall bladder. Otherwise, therapy is chiefly supportive and symptomatic. The protective value of a high carbohydrate diet is important. The value of insulin in this connection is still debatable. Much relief of pruritus may be obtained from administration of ergotamine tartrate, sodium thiosulphate, or calomel. Anemia can be treated with iron, or with liver extract, as suggested by Goldhamer. Diuretics may aid in eliminating or controlling ascites.

There is considerable weight of surgical authority behind the practice of incriminating the gall bladder and either removing or draining it in cases of chronic jaundice. It must be apparent from the foregoing statement that the procedure has small chance of success except in cases in which there is actual obstruction to the common bile duct or gross infection in the extrahepatic biliary passages. A positive cholecystogram has on more than one occasion been a factor which led to surgical treatment; our own experience leads us to believe that this is probably the last factor which should influence the surgeon. It must be emphasized that cholecystograms in the presence of chronic jaundice or hepatic disease generally should be interpreted most cautiously. Under such conditions the liver is probably unable to eliminate cholecystographic dye at a normal rate and, as a rule, the amounts of the dye which are concentrated in the gall bladder are insufficient to produce a shadow adequate for diagnosis. Even if calculi are demonstrated, their significance is debatable, whether pain has been noted previously or not. In other words, a decision to explore the biliary passages should be based entirely on clinical grounds. Furthermore, cholecystectomy or cholecystostomy in such cases has given indifferent results at best. However, in any case of chronic jaundice, especially if the jaundice is fluctuant or recurrent, the question of exploration must be carefully considered. In many cases it is difficult to determine if a silent stone is present in the common bile duct, and under such circumstances, the risk of operation is entirely justifiable.

A consideration of other surgical procedures may arise in the individual cases. Splenectomy may be considered in the exceptional case, but, as a rule, splenomegaly is purely secondary to the hepatic disease; therefore, the removal of the spleen seldom accomplishes such definite results as it does in hemolytic jaundice or splenic anemia. It may possibly lessen the amount of blood that must pass through the liver and thus reduce the load on the portal circulation. Omentopexy is sometimes considered in cases in which ascites is present. The value of ligation of collateral venous channels which lead to the esophageal plexus perhaps has not been fully explored; it may be a necessary procedure if there is repeated hemorrhage from esophageal varices.

SUMMARY

The term "biliary cirrhosis" implies that the toxic agent enters through the biliary ducts. This is true of the obstructive types of cirrhosis which have been briefly described. The toxic and infectious type and the type associated with chronic atrophy present the following features.

The etiology varies greatly. Hepatotoxins, metabolic intoxication, infections of the biliary tract, and gastro-intestinal tracts, and systemic infections are the cause of the condition in a large number of cases, but there is still a considerable number of cases in which the etiology is unknown. Patients who have this syndrome live for a long time and are resistant both to the disease and to the treatment. There often are entirely unexpected recoveries. In many cases the chief disturbance is in the excretory function of the liver; this is indicated by disturbances in the excretion of bromsulphalein and in the serum bilirubin. The pathologic findings, which vary with the stage of the disease at which the observations are made, do not differ significantly from those found in cases in which jaundice is absent. Finally, it is probably just as unwise to attempt an anatomic diagnosis and establish a prognosis on the basis of a single examination in such cases as it is to do so in a case in which there are signs of parenchymatous renal disease.

DISCUSSION

DR. ALBERT F. R. ANDRESEN (Brooklyn, New York): As I look at this and the previous paper, they have given us a clinical demonstration of the ability of the liver to regenerate itself, and also of the fact that this regenerated tissue can eventually take over the function of the liver, facts that have been demonstrated experi-

mentally in animals. In our acute cases what we attempt to do is to tide over the patient until the regenerated tissue can take over liver function in its entirety. In the chronic cases apparently the regeneration has kept step with, or has kept perhaps a step ahead of the destructive processes going on, accounting for the patient surviving so long.

Emphasis has been placed on the importance of a high carbohydrate diet and of intravenous glucose administration. I think not enough emphasis is being placed on the observations of Mann and Bollman that in hepatectomized animals the factor causing the most rapid destruction of the individual, the factor that apparently is responsible for the very rapid development of edema and ascites, is the ingestion of meat or meat extracts. This is equally true in the human. In the dietetic treatment of patients with destructive conditions of the liver, avoidance of animal protein (meat) and animal protein extracts, such as broth or soups, is fully as important as the pushing of carbohydrates and calcium.

DR. DAVID REISMAN (Philadelphia, Pa.): The right upper quadrant of the abdomen, which I have called the "Balkans of the body," presents us with more perplexing problems than any other anatomic region. And of all the problems that of chronic jaundice is the most tantalizing. Doctors Weir and Snell in their exhaustive paper show how complicated it is and from the large experience of the Mayo Clinic shed new light upon it. I am not sure but that the title of their essay might profitably be reversed, that is, instead of saying chronic hepatitis with jaundice, to say, chronic jaundice with hepatitis and other non-obstructive lesions. They would restrict the term biliary cirrhosis to that form of cirrhosis in which the toxic agent enters through the bile ducts. I wonder whether such a restriction is not a little too narrow. Is it not more likely that in the toxic cases the poison reaches the liver through the blood? In the so-called Hanot's cirrhosis, a condition which may not be a true clinical entity but in a sense is a type of biliary cirrhosis, the agent whatever it may be must reach the liver as it does the spleen by the hematogenous route. Perhaps the term biliary cirrhosis ought to be applied to that form of cirrhosis in which jaundice is an early and prominent feature and ascites, if it occurs at all, a late phenomenon. True biliary cirrhosis is rare in cases of common duct obstruction by stone. It is, I think, the general experience that mechanical biliary obstruction seldom causes cirrhosis of any kind. Rolleston has pointed out how rarely malignant disease of the pancreas with complete obstruction is associated with cirrhosis of the liver. Stricture of the common duct sometimes is attended by cirrhosis but the cause is probably some form of infection rather than bile retention *per se*.

Considering the frequency of gall stones and of cholecystitis, it is surprising how rarely the liver is the seat of any kind of serious injury. It is in cases with active infection, cholangitis and suppuration in the gall bladder, in which injury of the liver most frequently occurs. Dr. Reuben Ottenberg of the Mt. Sinai Hospital in New York was good enough to look over the records of that busy hospital. In 300 cases of liver disease, there were 10 that were recorded as biliary cirrhosis, in 6 of which the diagnosis was confirmed by operation or autopsy while in 4 it was purely a clinical opinion.

Because the liver is so tolerant—it must have enormous factors of safety since three-fourths of it can be cut away in an animal and the remainder will suffice for all purposes. I am not altogether in accord with the opinion of some of my surgical friends that the presence of gall stones is always and invariably an indication for operation. Dr. Chester Jones in his paper this morning also showed the high degree of liver tolerance that exists.

Doctors Weir and Snell have referred to the distress caused by itching. I believe generalized itching is almost the greatest physical suffering to which the human body can be put. Angina pectoris and coronary pains are intolerable but they pass either in life or death but itching may go on forever. For that reason I favor cholecystenterostomy even if the cause of the jaundice is irremovable, provided it is obstructive.

A number of years ago I wrote a little article on what I called "preicteric itching"—itching present in persons who a few days or weeks later developed jaundice. I have seen similar cases since that publication, which was made before we knew about the van den Bergh test. Perhaps there was a latent jaundice present. It is possible, however, that the itching in jaundice is not due to the bile pigments but to the bile acids or some other constituent of the bile. A fact that might seem to corroborate this idea is the frequent disappearance of the itching within twenty-four hours after the cholecystenterostomy long before there is any visible diminution in the icterus.

I am glad that Doctors Weir and Snell are focussing our attention on jaundice—perhaps their present and future studies will help us better to understand and to treat that important symptom.

DR. CHESTER JONES (Boston, Massachusetts): I am interested in the group that Drs. Weir and Snell have reported. A few years ago I collected 30 patients like this that I had been following for 10 years. I have continued to follow that group and now have several that have been jaundiced for between 15 and 18 years. I shall agree with Dr. Weir that the length of life that some of these patients will carry out is really quite surprising.

The important symptom that most of them complain of, I think, is weakness. Even if they live they are unable to do a full day's work in most instances. I think pathologically they fall into two groups. It may be of some importance to stress those two groups. The two extremes are an atrophic type of cirrhosis, based on original acute yellow atrophy, in which there is complete destruction of the normal architecture of the liver and a rather haphazard of hepatic tissue.

The group at the other extreme is one in which there is a true hypertrophic cirrhosis of the liver. It may be caused by obstruction of long standing or it may be due to infection. In these cases instead of there being a disturbance of the normal architecture of the liver there is a large connective tissue increase between the portal spaces as well as lymphocytic infiltration. In between these two extremes we get almost any variation that we may desire.

In the first group it is important to point out that catarrhal jaundice may be, and frequently is, a cause of the condition which may run on for years. There was an excellent review of cases brought out two or three years ago following an epidemic of catarrhal jaundice in Stockholm. If I remember correctly, prior to that epidemic there had been two or three cases of acute yellow atrophy annually reported to the medical examiner. Following this epidemic, there were 60 cases reported in one year. The pathologic findings in the autopsied cases were all those of acute or subacute yellow atrophy.

One of the cases I followed until two months ago had been jaundiced for 15 years. He and his brother became jaundiced in an epidemic of catarrhal jaundice. His brother lived three months, and this patient lived 15 years. He went through the entire gamut of hepatic failure, prolonged jaundice followed by the development of ascites, which subsequently disappeared. He carried on a fairly active life for almost six years after the ascites was first noted.

The long period of survival is possible if they are well treated in the beginning stages of liver insufficiency. But, weakness and a persistent anemia that does not respond to treatment are two of the outstanding features.

DR. JAMES F. WEIR (closing the discussion): I wish to thank the gentlemen who have so kindly discussed this paper.

Dr. Riesman mentioned the severity of the pruritus that many of these cases have presented. Some of the chronic cases of jaundice without obstruction have presented pruritus as a particularly prominent feature, and almost anything one can do has not been of benefit. In the early days some of these patients with nonobstructive jaundice were subjected to cholecystogastrostomy without any change in the symptoms, particularly the pruritus.

In this group of cases we can emphasize first, that there are some that are related to gastro-intestinal infections; second, that biliary tract infection probably plays a minor rôle; third, that functional tests are not of much value except in the terminal states; and fourth, that most of the unknown types, as far as etiology are concerned, are forms of chronic atrophy.

Macrocytic Anemia in Diseases of the Liver: General Considerations*

By

DAVID H. ROSENBERG, M.D.
CHICAGO, ILLINOIS

THE impetus given to the study of the anemias, initiated particularly by the experiments of Whipple and Robscheit-Robbins and by the contributions of Minot and his collaborators, has served to focus attention upon the group simulating Addisonian, "pernicious anemia," and characterized by the presence of a macrocytosis. From the specific effect of liver in the treatment of pernicious anemia, it seemed evident that more careful studies of the morphology of the blood in hepatic disease were indicated.

Notwithstanding the early observations of Gram (1883) (1), Limbeck (1896) (2), Capps (1903) (3), Talley (1908) (4), Perrin (1908) (5) and those of later contributors, until recently, a macrocytic anemia associated with various forms of liver disease without hemorrhage, (cirrhosis, "catarrhal jaundice," obstructive jaundice, carcinoma) had been regarded as no less than unique. Yet from a review of the literature, more than 200 such cases have been recorded to date, and, unquestionably, many others have been observed but not reported.

In this presentation, it will be shown that a macrocytic anemia, or macrocytosis alone, is a common finding in advanced or widespread liver disease. Its characteristics and therapeutic responses will be reviewed and discussed, and its prognostic significance indicated.

AUTHOR'S STUDY

Complete blood counts including cell volume determinations were performed upon 66 selected patients, in whom the diagnosis of liver disease seemed beyond question. Of these, 42 were diagnosed hypertrophic portal cirrhosis, 4 atrophic portal cirrhosis, 3 hypertrophic biliary cirrhosis, 1 acute yellow atrophy, 10 toxic hepatitis, 3 carcinoma of the head of the pancreas and 3 diffuse metastatic carcinoma of the liver. Parenchymatous jaundice was present in 45 patients, the icterus index ranging between 18 and 187, and averaging 58. In 22 of the patients with jaundice, and in 9 others (cirrhoses), ascites were easily demonstrable. There was considerable variation in the duration of symptoms, being from 1 week, in the acute cases, to 16 years in the cirrhoses; the average for the entire series was 1.3 years. It is apparent from these data that this group as a whole represents advanced or widespread hepatic disease.

The detailed data and observations pertaining to 62 of these patients have been recorded elsewhere (6).

Incidence: Most of the reports that have appeared in the literature have been confined to single case studies or to observations upon small groups of patients. Hence it has been difficult to formulate a true appreciation of its incidence. Meulengracht (17) observed a macrocytosis in all cases of catarrhal jaundice, cirrhosis or hepatic tumor, when they were associated with intense icterus. Similarly, Schulten and Malamos (7) concluded from their studies, that in diffuse liver disease, especially with jaundice, macrocytosis is an almost constant finding. In a review of 100 cases of portal cirrhosis, King (8) alludes to no instance of macrocytic or hyperchromic anemia amongst 57 cases without hemorrhage. On the other hand, Fellinger and Klima (9) found a hyperchromic anemia in 18 out of 48 patients who had various grades of cirrhosis, and expressed the belief that practically all such cases would ultimately manifest this form of anemia. Cheney (10) reported an increased cell diameter in 36.8% of his cases of liver disease, and in 11 out of 12 with hematocrit studies the cell volume was greater than normal. Wintrobe (11) found a macrocytic anemia in 25 out of 132 patients (21.9%) with various types of liver disease, the macrocytosis having been observed only in cases of long standing and very widespread liver damage.

In our observations on 66 patients, a macrocytic anemia was noted in 58 instances (88%). Of the remaining 8, a normocytic normochromic anemia was found in 2 patients with hypertrophic and in 1 with atrophic cirrhosis; a microcytic hypochromic anemia occurred in 1 with hypertrophic cirrhosis, a normal blood count in another case of hypertrophic cirrhosis, and a macrocytosis without anemia in one patient with toxic hepatitis and in one with acute yellow atrophy. The degree of macrocytosis varied within wide limits, the mean corpuscular volumes ranging between 95.4

Approved by the Committee on Publications.

and 142.5 c.u., and averaging 113.5 c.u.* The red blood cell counts in this series varied from 1.09 to 4.97 million per c.mm., and averaged 3.45 million. It is worth observing that the 4 patients with the most advanced anemias likewise presented the highest degrees of macrocytosis, whereas the patient diagnosed as relatively early hypertrophic cirrhosis exhibited a normal blood picture. From Chart 1, it is seen that a rather

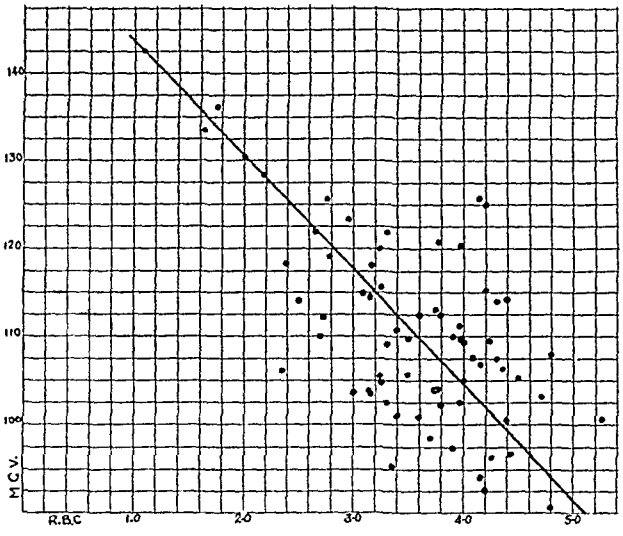

Chart 1. Showing the close parallelism between the degree of macrocytosis and the grade of anemia. As the anemia increases, the macrocytosis becomes more marked. The usual range of the anemia is clearly demonstrated. M.C.V. —mean corpuscular volume in cubic microns. R.B.C.— erythrocytes in millions per cubic millimeter.

close parallelism exists between the grade of anemia and the degree of macrocytosis. However, there was no absolute correlation in different patients between the extent of manifest liver disease and the degree of anemia and macrocytosis, some patients in the terminal stage presenting only a slight macrocytic anemia.

To determine with what frequency actual hyperchromia was encountered in our patients as a group is difficult, for so many presented a bilirubinemia, which, especially when marked, gives a fictitious reading with the Sahli hemometer. But of the patients with little or no jaundice, a hyperchromic anemia was found in 22.

Course: Relatively little has been written concerning the evolution and course of this form of anemia in hepatic disease. Wright (12) found a "tendency" toward the development of a macrocytosis in his 12 cases of cirrhosis. Other observers (9, 14, 15) reported a transition from a microcytic or normocytic anemia to a macrocytic type, concomitant with advancing liver destruction. In a study of experimental cirrhosis in rats, Higgins and Stasney (16) were able to observe the progressive development of a macrocytic anemia, the macrocytosis and the anemia increasing proportionately with the increase in the degree of cirrhosis. Further, Gram (1), Meulengracht (17), Stewart (18), Wintrobe and Shumacker (19) and others observed spontaneous remissions in patients improving or recovering from acute or chronic liver disease, and more recently, Wintrobe (11) noted remissions in 72% of his cases. Similar changes have been encountered amongst several of our patients, and are graphically represented in Chart 2. Of our cases of acute hepatic disease, a macrocytosis was present in one patient as early as the seventh day of illness; in another, it had disappeared within 2 weeks after improvement set in (6). In chronic liver disease the return to normal may take place rapidly or slowly, and may be only temporary, a relapse ensuing shortly thereafter. In none of our patients did the normal mean corpuscular volume become reëstablished. From the foregoing data, it is but a short step to propose that either an increasing macrocytosis or a progressive anemia, in the absence of hemorrhage, may be a useful prognostic criterion in the course of chronic liver disease.

Pathologic alterations have been observed in the blood forming organs of such patients. Bleichroeder (20) called attention to the red hyperplastic marrow in the long bones, particularly the femur, of many of his cases of cirrhosis, a finding which has been corroborated since then by others (9, 21, 22, 23, 11, 24). Isaacs (25) found an appreciable increase in the number of megaloblasts in the bone marrow of 6 patients with cirrhosis and macrocytic anemia, and Rossier (24) noted a decrease in the megakaryocytes. More recently, Rich (26) described multiple foci of normoblasts, macroblasts and myeloid leucocytes in the spleen of some patients with liver disease. It is of interest, therefore, that clinical evidence of active erythropoiesis, as indicated by a reticulocytosis, was obtained in the majority of our patients.

Hemosiderosis, particularly of the liver, spleen and bone marrow, has been observed by Bleichroeder, Rossier and others, and in these cases raises the question of the coexistence of cirrhosis with Addisonian anemia.

Diagnosis from Addisonian pernicious anemia: To distinguish clinically between a macrocytic anemia of the Addison-Biermer type and that accompanying atrophic or some cases of hypertrophic cirrhosis, without hemorrhage, may upon occasion challenge the diagnostic acumen of even the most astute physician. Zeigler (27), Roth (28) and Remen (29) have reported isolated cases in which a clinical diagnosis of Addisonian anemia was made without equivocation, but which at necropsy were shown to be atrophic cirrhosis.

Appearing in middle or late adult life, the semeiology may be identical, dyspeptic symptoms such as anorexia, nausea, vomiting, pain or irregular intestinal motions being present in both diseases. Glossitis and neurologic manifestations may develop in cirrhosis, although they are exceptional, the condition having been observed in but 3 of our series and only subsequent to protracted alcoholic debaucheries. The faintly icteric pallor and the excessive urobilinuria, so characteristic of pernicious anemia, are common findings in cirrhosis. Splenomegaly of a slight or moderate degree is not distinctive for either. But achlorhydria, almost invariably present in pernicious anemia, is far less frequent in cirrhosis, such having been found in 11 out of our 38 cases of cirrhosis which were tested with histidin (6). Although slight or moderate ascites may occur in pernicious anemia, it is found only with the extreme grades of anemia; other signs of portal obstruction are distinctly lacking.

Contrary to Addisonian anemia, in the majority of cases of liver disease, the anemia when recognized is of a slight or moderate grade; hence asthenia is a less

*Normal—80-94 c.u.

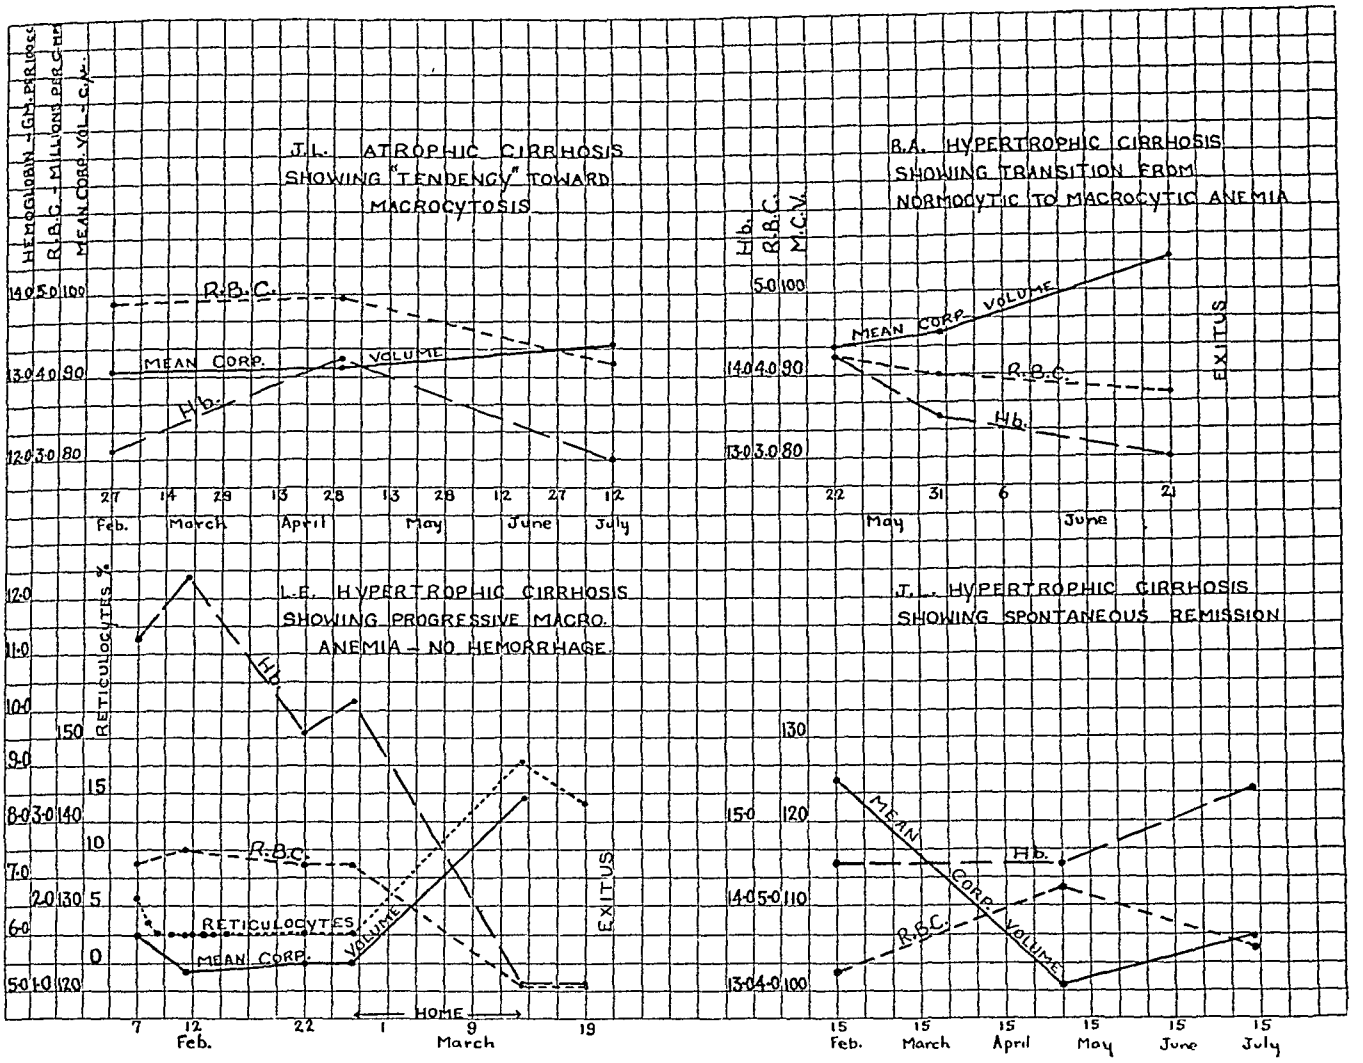

Chart 2. *Illustrating the evolution and course of the macrocytic anemia in liver disease.*

striking symptom. Blood films reveal a slight increase in the diameter of the erythrocytes, the size and shape of the cells being relatively uniform. Price-Jones frequency curves simulate those of equivalent degrees of pernicious anemia (19). In the more advanced anemias, a conspicuous macrocytosis with slight or moderate anisocytosis are in evidence. Poikilocytes and polychromatophilia are less frequent in liver disease, and microcytes and nucleated red cells are seen only occasionally. In one of our patients, giant platelets were noted, and in a small minority of our cases, a leucopenia with a relative lymphocytosis was found. With such similarities, it is apparent that in the differential diagnosis of Addisonian, "pernicious," anemia, particularly in the less advanced forms, thought must be given to the possibility of hepatic cirrhosis.

Treatment: Various results have been obtained through the administration of liver, parenterally or orally. Perrin (5), who employed liver extensively in the anemias of liver disease, noted distinct hematologic improvement, and in some cases, even a polyglobulia. From the reports of 13 cases treated with parenteral "primary anemia" liver extract (13, 30, 19, 11), definite remissions were produced in 8. Yet other investigators (9, 31, 10) consistently noted little or no response.

Of our 7 patients whose erythrocytes ranged from 1.85 to 3.14 million per c.mm. (average 2.38 million) and who were treated with potent liver extract, a reticulocyte rise occurred in 4, being only slight in 3 of these. A moderate increase in red blood cells was noted in 1; in 3 others a slight but significant rise appeared, ultimately returning to the initial level in one despite continued therapy; in the remaining 3, no response was noted. In one patient the blood picture seemed to be maintained at a constant level, for after discontinuing liver therapy, the erythrocytes and hemoglobin dropped rapidly. In none were the hemoglobin values affected.

In explanation of the variability in response to liver therapy, it has been suggested that the liver may play an important *rôle* in the intermediary metabolism of liver extract, little or no effect being evoked in cases with extensive liver disease. Or, perhaps in some, doses larger than those customarily exhibited might have been more uniformly effective.

Cheney (10) observed striking improvement with "secondary anemia" liver extract plus iron, but this did not obtain in Wintrobe's (11) case. In only

1 out of 3 patients (11) was vitamin B therapy efficacious, whereas stomach extract proved valueless in 2 instances (13, 19).

Pathogenesis: The origin of this anemia in liver disease has called forth interesting speculation and thought. Naegeli (32) hypothecated an endogenous toxin as its cause, but no evidence has been adduced in its favor. Meulengracht (17) contended that the macrocytosis was due to a swelling of the erythrocytes, resulting from physico-chemical changes in the blood. Finding a direct relationship between cell size and the degree of icterus, he suspected the bile salts as the provocative agents, but our own failure to observe such a correlation tends to negate this possibility.

More recently it has been pointed out that the common factor in the development of a macrocytic anemia is a deficiency (33, 34) of the hematopoietic principle, either through its defective formation, absorption or utilization. Ivy, Richter and Kim (35) have demonstrated that the active substance is stored in the liver, and Goldhamer, Isaacs and Sturgis (30a) have shown that it is either reduced or absent in hepatic cirrhosis with macrocytic anemia. These observations in conjunction with the experimental results of Higgins and Stasney seem to indicate that the view of a deficient storage of the hematopoietic principle by a diseased liver is the most tenable explanation of today.

However, some of our observations (6) suggest that the explanation may be more complex than that presented above, and that the development of a macrocytic hyperchromic anemia may proceed in at least two stages, either simultaneously or consecutively: *first*, a swelling of the erythrocytes may occur, possibly as a result of a lowered colloid osmotic pressure secondary to a decrease in serum albumin, the latter commonly found (36) in advanced liver disease; and *second*, when the store of hematopoietic principle in the liver becomes sufficiently depleted, true macrocytes rich in hemoglobin appear in the peripheral blood. Careful follow-up studies of the blood, especially in cases of less advanced chronic liver disease, may reveal significant data and may aid in the elucidation of these changes.

SUMMARY

The incidence, course, prognostic significance, pathologic findings, treatment and pathogenesis of the macrocytic anemia occurring in advanced or widespread liver disease are discussed. The similarities and dissimilarities to Addisonian pernicious anemia are reviewed. Attention is drawn to the importance of considering chronic liver disease, cirrhosis in particular, in the differential diagnosis of mild and moderate grades of Addisonian "pernicious" anemia.

DISCUSSION

DR. M. M. WINTROBE (Baltimore, Maryland): Dr. Rosenberg has presented a very able summary of the literature and has made some very interesting observations of his own.

He has emphasized the fact that in many instances the differentiation of pernicious anemia and the macrocytic anemia of liver disease may be difficult. I should like to stress, however, that this is the unusual rather than the usual course of events. In most of these cases the picture of liver disease is a very clear and definite one. In fact, I think the failure to recognize until recently that macrocytic anemia occurs in some cases of liver disease is largely due to the fact that the picture of liver disease is usually so prominent that complete studies of blood often are not made. These patients may show variable degrees of jaundice or ascites, large livers and impairment of liver function.

I am rather surprised at the very high incidence of macrocytosis in Dr. Rosenberg's cases.

(Slide) We have made a clinical and pathological study of 132 cases of liver disease of all kinds, and 34 of these were studied after death, the tissues being examined microscopically in these cases. We found that macrocytic anemia was present in 43 of the 132 cases. However, I think that some of these cases should be excluded from the series for various reasons.

First of all, some of these were instances of hemolytic anemia, which in itself might cause macrocytosis. These cases very probably do not belong in the group under discussion.

Furthermore, in a number of cases the mean corpuscular volume was only slightly in excess of normal and in some instances was only determined once.

I should like to emphasize that although the determination of mean corpuscular volume is of considerable value it is also open to a good deal of error and one ought to be very cautious in the interpretation of the results unless they are confirmed repeatedly. Incomplete packing of the red cells, or a slight difference in the red cell count may give misleading results. In my own experience errors tend to give a macrocytosis rather than the opposite.

For these various reasons we excluded 18 of our cases. This leaves very definite macrocytosis in only 25 cases, or 22 per cent.

I should like to ask Dr. Rosenberg whether pathological studies were made of the livers of his cases to determine the correlation of the nature of the liver damage with the type of anemia found.

This is a point which I would like to emphasize, namely, the relation of the type of liver disease to macrocytosis. From these figures you will see that it was in the cases of cirrhosis that the incidence of macrocytosis was high. In the cases of malignancy with cirrhosis, macrocytic anemia

was very frequently found. This type of anemia seems to occur in cases of liver disease in which the liver disorder has been of long duration and is extremely widespread, a finding which rather tends to support the hypothesis that the anemia may be the result of faulty storage or formation of anti-anemic principle.

In observations which we are going to report this afternoon at the meeting of the American Society for Clinical Investigation, experiments were carried out in dogs and in rabbits which tended to corroborate these findings, namely, that the macrocytosis appeared only in those instances in which the liver damage was of long duration and extremely wide spread.

DR. DAVID H. ROSENBERG (Chicago, Illinois, closing the discussion): I think it is worthy of emphasis that the type of patients which we selected for study did represent, we felt, advanced and widespread liver disease, as shown by the data presented at the beginning of the paper.

Furthermore, Cheney, of California, in studying the cell volume in 12 cases of liver disease, found 11 of these patients with an abnormally high cell volume, whereas when actual cell diametric measurements were made, macrocytosis was found to be present in 37 per cent of all of his cases.

Post mortem studies were available in nine patients and of these, one was a case of acute yellow atrophy and the other eight, cirrhosis. All of them showed extensive and widespread disease of the liver.

Concerning the relationship of the nature of liver disease to the development of macrocytosis, I agree that the macrocytosis occurs only when one finds advanced or widespread liver disease.

Anemia and the Gastro-Intestinal Tract*†

A Synopsis

By

GEORGE R. MINOT, A.B., M.D., S.D., F.R.C.P. (Edin.)

BOSTON, MASSACHUSETTS

NUMEROUS concepts of an association of anemia and the gastro-intestinal tract and its contents have been expressed in various ways for more than a century. It is, however, only during recent years that it has been clearly recognized that anemia often is dependent on defective nutrition, and that derangements of the gastro-intestinal function can be responsible for impoverishment of blood formation. So far as the digestive tract itself is concerned, the focus of attention has been directed to the stomach. Even as long ago as 1855, the year that Addison's second, but best known, description of "idiopathic anemia" (pernicious anemia) was published, C. Handfield Jones (1), who studied the stomach histologically, wrote after describing the case of a "very anemic" man, 62 years old, with "marked atrophy of the glandular tubes" [of the stomach], "Here is a case of extreme wasting of the secretory structure of the stomach coinciding with like wasting of the blood without any apparent cause." He also mentions "That inflammation may and often does produce atrophic changes is perfectly true, but I can not but regard it as a mischievous error to assume that it is the only or the most frequent cause of such changes." Further on he writes, "These morbid changes I believe to be coincident results of depraved nutrition . . . ." The last remarks are of historical interest in relation to today's knowledge that gastric atrophy and achlorhydria may develop with dietary deficiency.

A prophetic statement was made by Austin Flint (2) in 1860 when he wrote, "Nor is it difficult to see how fatal anemia must follow an amount of degenerative disease reducing the amount of gastric juice so far that the assimilation of food is rendered wholly inadequate to the wants of the body."

Samuel Fenwick's (3) studies represent the significant pioneer work in this field. In 1870, he described a typical case of pernicious anemia with great atrophy of the "secreting tubules (of the stomach) converted into a mass of connective tissue." He showed that pepsin was absent. He wrote, "The progressive atrophy of the stomach had prevented the digestion of the albuminous materials of the food." Fenwick apparently considered that this was the cause of the anemia and wrote that "Perhaps future investigators may prove that the anemia [in another type of case] arises from a coexisting atrophy . . . of the stomach or other parts of the digestive canal." In subsequent papers and in his book published ten years later, he records further distinctive observations and remarks concerning the relation of the blood to the state of the digestive tract. Many studies concerning the stomach in pernicious anemia followed by such men as Cahn and von Mering, Kinnicutt, Quinsel, Faber and Block, and Hurst. There are also many early references, mostly rather vague in nature, to the relationship between the gastro-intestinal tract and hypochromic anemias, especially chlorosis. There was a waxing and waning interest in this subject in general until 1928 when Castle, after subjecting to experiment his brilliant original ideas, proved with his collaborators the important *rôle* of a factor secreted by the normal stomach which is essential for normal blood formation.

(Following this introduction there was reviewed with a series of 30 lantern slides, first, problems concerning macrocytic anemias due to deficiency of material effective in pernicious anemia, and then various aspects of hypo-

†The Abbott Lecture: Established by Frank Smithies, M.D., Chicago, 1929, but now maintained by the Association.

Delivered at the Thirty-ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936.

chromic anemia due mainly to iron deficiency. A synopsis of the lecture is given below):

THE MACROCYTIC ANEMIAS OF NUTRITIONAL DEFICIENCY

Pernicious anemia and related macrocytic anemias have been shown by Castle to be dependent upon a nutritional disturbance conditioned by the state of the gastro-intestinal tract. The normal individual can derive material from food needed to prevent pernicious anemia by means of gastric digestion. Deficiency of the gastric factor, of the dietary factor, or of the material within the body proper originating from the interaction of these two factors leads to macrocytic anemia. The factors may interact somewhat in accordance with the law of "mass action." Disorder of the intermediate or internal metabolism of "liver extract" may perhaps occur. It is unreasonable to blame faulty storage in the liver alone as a cause of macrocytic anemia for the potent material occurs in other organs, such as the kidney and brain.

The varying and atypical results produced by the parenteral injection of gastric juice await elucidation. The observations must be evaluated with the recognition that there are many unrelated substances that can induce non-specific reticulocyte responses.

Greenspon (4) has recently claimed that the gastric factor is a hormone effective directly on blood production. He asserts that in Castle's experiments pepsin destroyed the gastric factor when gastric juice was administered alone, and that beef muscle and certain other foods act simply to adsorb pepsin rather than that they contain a dietary factor. There are various reasons for considering that Greenspon's contentions are unlikely. For example, (*1*). Helmer, Fouts and Zerfas (5) have shown that depepsinized and neutralized gastric juice is inert and that its incubation with small amounts of "fraction G" liver extract of Cohn increases this material's potency several times. (*2*). Responses have been shown (6) to occur when gastric juice and suitable food are fed over six hours apart. Thus, the interpretation of a positive response to gastric juice alone is invalid when food is given four hours after gastric juice, as took place in a crucial experiment Greenspon performed.

Residual amounts of intrinsic factor are present in most cases of pernicious anemia so that a continuously progressive decrease of the blood to the vanishing point does not occur. It takes less liver extract to maintain one million than five million red blood cells. A slight increase of intrinsic factor with a good diet can permit a higher blood level, but it takes much more to maintain an entirely normal blood picture.

To believe that polycythemia is due to excess of liver extract or gastric factor necessitates the assumption that polycythemia can be induced in any normal individual by administration of liver extract or of stomach tissue. This can not be done. The red cells may rise temporarily above normal in recovery from macrocytic or hypochromic anemia simply because the volume of the marrow subsides more slowly than delivery of its contents.

Meulengracht has shown the relatively high potency of the pyloric and cardic portions of the stomach and of the duodenum for the gastric factor. The gastric factor is perhaps secreted by aberrant gastric tissue as in Meckel's diverticulum (Morrison (7)). Gastrectomy leads rarely to macrocytic anemia; very frequently to hypochromic anemia. The secretion of the gastric factor by the duodenum may explain the former state of affairs. The latter condition is associated with defective iron absorption which is discussed further on. The rapid intestinal emptying and modified diets that occur in such instances play a *rôle*. The store of liver extract in the normal body can be estimated as sufficient to prevent pernicious anemia for one or more years.

The repair with therapy of lesions in the stomach is comparable with those of the tongue, as shown by Chester M. Jones. Previous observers studied the gastric mucosa in relapse. Jones has shown the change "from the appearance of atrophy to that of normal gastric mucosa" following liver therapy; an epithelial change due to replacement of a specific deficiency rather than the healing of an inflammatory lesion. In spite of this, achlorhydria almost always persists and apparently the intrinsic factor rarely increases more than slightly.

The conditions causing failure of gastric secretion must be sought. Gastritis, as Faber and Hurst believe, may be important. An hereditary susceptibility may exist. Defective diets can produce widespread changes in the alimentary tract. Miller and Rhoads have produced achlorhydria, lack of intrinsic factor, and macrocytic anemia in pigs by diets defective in vitamin B_2 or a closely related substance. Thus, a non-infective condition can create the defect seen in pernicious anemia. Bad diets can lead to achlorhydria in man. Certain alterations in various hormone actions also can lead to achlorhydria. The effect of anemia, *per se*, on gastric function should not be lost sight of. Dietary deficiency certainly intensifies the picture of faulty gastric function. The applicability of Miller and Rhoads' studies to the etiology of cases of macrocytic anemia arising in the tropics and shown to be due to defective diet can scarcely be doubted, but how far dietary deficiency is operative directly in all cases of macrocytic anemia awaits further study.

Defects of absorption may contribute to deficiency of active products in anemia as in other deficiency states. There is a lamentable lack of knowledge of alimentation. There are innumerable factors that have to do with absorption. The fact that *usual* doses of liver extract given intramuscularly are sometimes maximally effective when treatment by mouth fails suggests that material is not adequately absorbed. This is even more likely because of the association of pernicious anemia with intestinal stenosis and short circuits of the intestine, and its origin with protracted diarrhea as in bacillary dysentery. Occasionally, a patient with an intestinal short circuit, maintained with difficulty on liver extract administered orally, is able to maintain his blood without taking liver extract after the intestines have been returned to essentially their normal state by operative procedure. This is further evidence of faulty absorption. In many instances probably the state of nutritional deficiency leads to gastro-intestinal defects hindering absorption and thus intensifying the disease process.

Tests for defective absorption are needed. The absorption of iodine is often delayed in deficiency conditions and becomes more rapid as a deficiency is met. The delay is perhaps a rough measure of disturbance of the absorptive ability of the upper small intestine (8). The degree of eosinophilia developed from the feeding of raw liver can not at present be definitely related to intestinal permeability. Studies by intestinal

intubation may be shown to be of value. X-ray observations can indicate changes of tone, and activity which may adversely affect absorption of dietary factors.

In diagnosis it must not be forgotten that frequently gastro-intestinal symptoms occur for years before anemia is obvious and that gall bladder disease is common in pernicious anemia.

Tongue, aesophageal, gastric, and intestinal lesions may appear in the macrocytic anemias of nutritional deficiency when the blood is normal or essentially so. Their occurrence is dependent upon activity of the intrinsic factor. In sprue, such lesions are more prominent and extensive than in pernicious anemia and often occur without macrocytic anemia. Liver therapy, however, heals the lesions and their presence demands enough potent material to banish them, disregarding the state of the blood. Indeed, the effect of liver and stomach treatment on the gastro-intestinal tract in *early cases of pernicious anemia, sprue, and certain* atypical cases with gastro-intestinal symptomatology is striking.

Iron deficiency anemia may develop in sprue and during liver therapy in pernicious anemia when iron will alleviate the anemia, but liver must be given to affect the gastro-intestinal symptoms or for maintenance of health.

HYPOCHROMIC ANEMIA

Hemoglobin deficiency is the feature and may arise from lack of material other than iron needed to build the hemoglobin molecule. There are many other factors than iron that can influence hemoglobin production. Iron, however, can cure many cases of hypochromic anemia and it has been shown in man (Heath, *et al*) and dogs (Whipple, *et al*) (9, 10) that, following injection, iron will be returned quantitatively as new formed hemoglobin. In large part the metabolic need in these cases is satisfied by iron. When this need is met the blood-forming organs can respond to the real stimulus which is the anemia. There has been much discussion regarding the most effective type of iron (11). In dogs, Whipple has shown the determining factor is the metal iron, and such seems to be the case in man when iron is given parenterally. In human disease, it appears that ferrous salts are often more effective by mouth than ferric salts, as Ashwell suspected in 1836; and that disorder in the intestinal tract may increase the difference between the effectiveness of the two types. It remains, however, a fact, as mentioned by Osler in 1885, that the important thing is to administer enough of a given kind of iron rather than to debate on what is the smallest dose of iron in some particular form that gives maximal effects.

Names have tended to obscure the close etiological relationship of the various varieties of hypochromic anemia associated with iron deficiency. The basic mechanisms for the origin of this type of anemia are an inadequate intake for the needs of the given organism, faulty absorption or utilization of iron, and loss of this element from bleeding or from transfer to a foetus. As in other deficiency states in anemia, infection, severe damage to organs, and the like may inhibit nutrition and hinder the action of such therapeutic agents as liver extract and iron. In any given case usually several factors are operative and occasionally there occurs in the same individual a deficiency of both iron and the principle effective in pernicious anemia. Rarely one individual may pass through life and be said to have had each one of the varieties of hypochromic anemia mentioned below, which simply implies that throughout life she had an inadequate supply of iron and material for hemoglobin manufacture for her given needs.

The answer to why hypochromic anemia is much more common in women is to be found largely in the fact that under ideal circumstances woman requires for health about four times as much iron as man, up to the age of the menopause.

The nutritional anemia of infants, especially prevalent in artificially fed babies, is dependent on insufficient storage and intake of iron to meet the demands of growth.

Chlorosis, as Stockman noted in 1895, develops at an age when the need for iron rapidly increases due to growth and menstruation; the latter must be offset by the intake of 1 mgm. of iron a day per year. If one adds the growth requirement for the age fourteen to fifteen to the loss from menstruation there is about a 1000 cubic centimeter drain of blood on the iron store. Add to this a poor diet, infections, altered digestion and absorption, and recognize the vicious circle that arises with the development of anemia; then the reasons for iron deficiency of the type called chlorosis seem evident. Heath and Patek (12) have set forth evidence for this point of view. The condition, in part, has disappeared because some cases called chlorosis are now recognized as peptic ulcer, tuberculosis, etc.; and, in part, probably because of the greater frequency of high iron diets. There are many cases of mild anemia today at the chlorosis age; disordered digestion is sometimes given as the cause. It is also not rare to see cases of severe anemia at this age which are apt to be given other names than chlorosis, partly because the causes, such as depraved appetite, slight excess menstruation, etc., are recognized.

The common hypochromic anemia of pregnancy can often be related to the extra demands for iron and to the defects of gastric secretion. It can be prevented by administration of iron.

So-called "idiopathic" hypochromic anemia, very rarely seen in males, can be accounted for particularly by the accumulative effects of the factors mentioned; and with onset of the condition these same causes become aggravated, thus intensifying the deficient state. It is common to find that these women have had gastro-intestinal symptoms for years and present the picture of "chronic intestinal nervous invalids," who have often partaken of diets low in protein and iron for a long time. Altered bile secretion may occur and, among other gastro-intestinal defects, may perhaps hinder the absorption of iron. The flabby atrophic tongue, seldom raw, and achlorhydria with increased mucous secretion are features. The Plummer-Vinson syndrome, originally described by Brown Kelley and D. R. Paterson in 1919, seems to be in these cases dependent on esophageal spasms and webs due to atrophic and associated changes of the epithelium and underlying structures. Indeed, it is alterations of this type that are to be found in very severe cases throughout the intestinal tract, as reported by Schmehle and Schmid (13). These alterations are nutritional, not primarily inflammatory. Full doses of iron totally change the picture; the improvement in gastro-intestinal symptomatology and appearance of the tongue being fully as striking as the improvement in the blood. Achlorhydria is prone

to remain present. It is yet to be proved exactly what factor is responsible for the gastro-intestinal lesions. The better appetite developed and better diet soon taken, once the patient receives enough iron, make it seem possible that numerous dietary factors may play a *rôle*. The symptoms and signs referable particularly to other ectodermal structures, such as the defective nails and atrophy of skin, and the readily bleeding uterine mucosae and ease of skin capillary leakage, are also dramatically affected by iron administration.

In a rare case of *polycythemia* one may find achlorhydria, atrophic tongue, and such gastro-intestinal symptoms as nausea, flatulence, and constipation. In such cases the color index is distinctly low although the red cell count may be well over 6,000,000 per cubic millimeter. These cases probably represent instances of iron deficiency occurring in the face of increased red cell production.

Chronic blood loss by itself is a common cause of hypochromic anemia. Iron therapy is always effective and the liver fraction insoluble in 70 per cent alcohol (not liver extract effective in pernicious anemia) can also enhance hemoglobin regeneration. In diagnosis it may be said that, with proper exceptions, severe hypochromic anemia in a male, which at first appears to be of obscure etiology, will after proper study often be shown to be due to recurrent asymptomatic blood loss from the gastro-intestinal tract.

The relation of the gastro-intestinal tract and its contents to iron deficiency anemia is a significant one. A host of factors bear on this subject. One must distinguish between effects being primary and contributory causes. Disease itself causes motor and secretory dysfunction and thus sets up a vicious cycle. Whatever leads to rapid gastric or small intestine evacuation and loss of tone diminishes the amount of iron taken into the body from the amount available in the diet.

Iron in food is present as ferric iron. The normal availability of food iron is sometimes less than fifty per cent of the iron contained in a given food. Iron is absorbed as ferrous iron. During digestion, the combined effects of low oxygen tension, abundance of readily oxydizable substances, and an acid reaction provide conditions in which conversion of ferric to ferrous iron is made likely to occur. Whatever handicaps diffusion of ferric salts decreases their effectiveness on oral administration. Certain mixtures of food may handicap the absorption of iron. The amount of phosphorus in milk as contrasted with that in orange juice can act to bind appreciable amounts of iron as insoluble salts (14). There are substances such as chlorophyl that appear to potentiate the action of iron. Factors that may enhance and hinder the utilization and absorption of iron require study, while the whole problem of iron metabolism and its interrelations to other factors that influence hemoglobin regeneration is far from solved.

Hypoacidity and anacidity may be considered to play a part directly or to indicate a significant disturbance of absorption capacity of the alimentary tract. Iron is absorbed particularly in the upper small intestine and an acid medium favors the process. If no acid is poured from the stomach into the duodenum the contents will tend to be less acid than normally, and thus iron absorption can be handicapped. The lack of hydrochloric acid and the gastric enzymes can decrease the ease with which iron is liberated from the complexes which contain it in the food. Achlorhydria may be a sign of other defects such as hasty peristalsis, atony, or pathological changes in the gastric mucosae or small intestine which may act unfavorably for iron absorption. Excess of mucus, often present with achlorhydria, can firmly absorb iron and thus perhaps render its absorption difficult.

The action of achlorhydria to antagonize the absorption of iron is also reflected from therapeutic studies in man. It appears that cases of "idiopathic" hypochromic anemia with achlorhydria usually require distinctly larger doses of iron for hemoglobin to regenerate at a maximal rate than cases of hypochromic anemia without achlorhydria, as for example especially those due only to chronic blood loss. Small doses of iron in the former condition frequently have essentially no effect at all while they can cause in the latter type of case distinctive hemoglobin increase but at a submaximal rate.

The types of anemia mentioned—those due to deficiency of material derived from food—will not arise with a healthy intestinal tract, a proper diet for the needs of the given individual at each period of life, and with the absence of abnormal blood loss or factors acting to inhibit nutrition. Much suffering from anemia can be prevented if every person, especially women, takes an optimal diet throughout life. Also, the establishment of early diagnosis followed by proper treatment for each and every aspect of the given individual's case will lead to the prevention of many severe cases of anemia. There is certainly an important interrelation of food, stomach, and intestine in the maintenance, not only of the blood, but also of the integrity of the normal individual.

Intubation Studies of the Human Small Intestine: VIII. - Miscellaneous Observations*

By

T. GRIER MILLER, M.D.

W. OSLER ABBOTT, M.D.**

and

W. G. KARR, Ph.D.

PHILADELPHIA, PENNSYLVANIA

IN May, 1934, Miller and Abbott (1) described a technique for the rapid introduction, under fasting conditions, of a double-lumened rubber tube into the upper intestinal tract of man and referred to the possibility, by such a method, of studying the secretory and motor functions of the human bowel. Scheltema (1908) (2), Einhorn (1919 and 1921) (3, 4), and Buckstein (1920) (5), had previously accomplished intestinal intubation, but their tubes were of small calibre, required much time for introduction and were designed only for the injection of solutions or suspensions into the bowel. Both Buckstein and Einhorn, however, referred to the possibility of the aspiration of intestinal contents, and, in 1930, Thompson, Einhorn and Coleman (6), using the Einhorn jointed tube, succeeded in aspirating both small and large intestinal contents for a study of the bacterial flora. Jones (7), so far as we know, was the first (1931) to introduce into the lower ileum and colon a tube with an attached balloon, but his apparatus provided no means for the aspiration of intestinal contents.

The chief claims for the original technique developed in our Clinic were that, under strictly fasting conditions, it permitted intubation of the small intestine within 4 to 6 hours and that it at the same time provided a means for exhaustive study of the bowel under essentially normal conditions. These purposes were accomplished by the attachment, at the distal end of the tube, of a balloon which could be distended when the duodenum was reached and which then served as a foreign body that was readily carried along aborally by peristaltic waves. At the same time, by having the tube double-lumened and of adequate calibre, aspirations and injections easily could be made through the lumen that was not connected with the balloon, while the balloon itself could be used to record pressure changes within the bowel.

Since then the apparatus has been modified and the technique perfected (8, 9) so that the entire small intestine usually may be intubated within 3 to 4 hours; so that specimens of the contents may be obtained under conditions of constant but slight negative pressure; so that pressure changes within the bowel may be graphically recorded while the intestinal activity is being observed under the roentgenoscope, and so that a segment of the bowel may be isolated between balloons, its uncontaminated secretion obtained and measured and its absorptive power tested.

It is admitted, however, that the method is not as yet strictly practical for routine use and that it requires considerable experience and much time and patience on the part of the investigator. Some failures inevitably occur, but in over 300 attempts at intubation, mostly on new subjects, Abbott has been successful in 70 to 80%. Often, even on the first attempt in a new subject, the tube reaches the duodenum within 10 minutes, the jejunum within 20 minutes and the lower ileum within 2 to 3 hours.

AUTHORS' STUDIES

At this time we wish to refer very briefly to certain observations that have been made in our Clinic by this technique, some of which have been published, and to point out other lines of clinical investigation that the method seems to render feasible.

Karr and Abbott (10) have already reported on certain chemical studies of the normal intestinal contents under fasting conditions and as influenced by the oral administration of acids, of alkalies and of water. They have confirmed the results of animal investigations, showing that, in the normal under fasting conditions, the reaction of the contents of the duodenum is usually slightly acid, while that of the jejunal and even the ileal contents is slightly acid to neutral, rarely alkaline; that the osmotic pressure of the duodenal contents is usually hypotonic, but that as lower levels are reached approximate isotonicity with the blood plasma is attained.

Miller and Karr (11) have shown that variations in the reaction of the intestinal contents are related not only to variations in the reaction of the stomach contents but also, and perhaps chiefly, to variations in the motility of the contents of the stomach and of the intestine. Thus, in a hyperacidity case (11, Exp. 39) the jejunal contents were approximately neutral until a gelatin solution was orally administered, whereupon, though such a protein solution would tend to neutralize the gastric acid, a distinctly acid reaction of the jejunal contents resulted: this was coincident with an increased rate of flow from the stomach. A similar increase in the acidity of the jejunal contents occurs for a time in normal cases after the administration of water and is coincident with an increased rate of gastric evacuation (10, Fig. 4). In such instances, however, the motility is soon diminished and the reaction of the intestinal contents promptly comes back to approximately neutral. Furthermore, when a highly

Approved by the Committee on Publications.

acid solution was administered to an achlorhydric subject (11, Exp. 28) no increase in the acidity of the ileal contents occurred at any time, presumably because evacuation from the stomach was sufficiently slowed to permit neutralization before the contents reached that level.

Thus, apparently it is only for a short time that the stomach, even when its contents are hyperacid, evacuates them rapidly enough to alter the intestinal reaction; then adjustments are made which restore the normal fasting reaction of the intestinal contents. Pylorospasm or duodenal control of gastric emptying is no doubt one of the biologic mechanisms designed to bring about this return to a normal reaction. Such control of gastric evacuation is observed clinically in certain cases of hyperchlorhydria and experimentally after the oral administration of various hypertonic solutions. Probably in achlorhydric subjects with diarrhea the administration of a strong hydrochloric acid solution sometimes has its beneficial effect by calling into action such duodenal control of gastric emptying.

When, on the other hand, the gastric contents of a normal subject are partially neutralized by the administration of a *hypotonic* solution of sodium bicarbonate, a rapid gastric evacuation and a rapid rate of flow through the intestine occur. When, however, the alkaline solution is *hypertonic*, the contents are evacuated slowly (10, Fig. 3). Thus one has an explanation for the laxative effect of a small dose of sodium bicarbonate in some individuals and for the fact that others may habitually take large doses without any stimulating action on the bowels. In like manner, water on an empty stomach may have a laxative effect by reducing the acidity and the tonicity of the stomach contents and so leading temporarily to a rapid rate of flow through the bowel.

These considerations lead one to wonder what occurs in the intestinal tract after the ingestion of ordinary food substances. Do the contents then maintain a neutral reaction and isotonicity with the blood plasma? Let us consider for the moment only the carbohydrate foods. In the first place, most of the natural foods that contain carbohydrate, such as milk, breadstuffs, vegetables and most of the edible fruits, are hypo- or isotonic. When certain fruit juices, high in sugar, or hypertonic solutions of sugar itself are ingested several mechanisms, similar to those for excessively acid or excessively alkaline solutions, seem to be brought into action to prevent entrance of the gastric and duodenal contents into the bowel in such a state. Ravdin and his co-workers (12) have demonstrated in animals that in no matter how concentrated a form glucose is administered to the stomach it becomes isotonic before it passes into the intestine. We (13) have shown the same phenomenon in man, have demonstrated that a further decrease in concentration occurs as the glucose passes through the duodenum and that the percentage concentration is even further reduced as lower levels of the intestine are reached, even to less than one per cent in the ileum. Under such circumstances isotonicity is maintained by variations in the electrolyte content (10).

Having shown, therefore, that ordinarily glucose appears in the intestine in less than 5.4 % concentration (isotonic solution), we next have attempted to determine its rate of absorption, confining most of our investigations to solutions at or below that concentration. Using isolated loops of bowel, into which were introduced 50 c.c. amounts of solutions of varying strength and removing the residue after fifteen minutes, we have demonstrated an increase in the rate of absorption with an increase in the concentration of the glucose solution.

We have only a few observations on the fate of hypertonic solutions of glucose in the intestine. It seems reasonable, however, that after the ingestion on an empty stomach of very sweet foods, such as orange juice, berries, preserved fruits or candy, some early escape into the intestine of sugar at a higher concentration may occur. Our data suggest that the intestine reacts to such a hypertonic material by an outpouring of fluid into the bowel, by increased peristalsis and motility and by the secretion of mucus. These reactions doubtless account for the clinical observation that some persons develop a diarrhea after taking such substances. Such diarrhea may also be dependent in part on changes in the tonus of the intestinal musculature. Some experiments on the intestinal action of morphine by Abbott and Pendergrass (14), using our technique of intubation, have suggested that the effectiveness of a substance upon intestinal motility may depend as much upon its action on muscular tonus as upon the height and frequency of peristaltic waves. This deserves further study, and the combined use of the multiple-lumened tube and roentgenoscopy seems to offer a means for such investigation.

The technique has also presented an opportunity to restudy the reference of pain from various points along the small intestine. Such studies were previously made by Jones (7), utilizing a balloon on a single-lumened tube; but our results, though in a measure confirmatory, show variations that deserve consideration. He was interested chiefly in pain produced by distension of the balloon when in the large intestine, but stated that when the balloon was distended in the jejunum or ileum pain for the most part was referred to the mid-line just above or below the umbilicus respectively; sometimes to the back. Our method has been to distend the balloon, while the subject was under the roentgenoscope, until discomfort was produced: at that time marks were made on the screen to indicate the exact location of the balloon and the point at which the subject with his own finger localized the pain. Reference to Chart 1 will show that the marks were superimposed only once, but that in the majority of instances pain from the jejunum was referred to a point above the umbilical line; from the ileum, to a point below that line. More specifically, when the balloon was in the jejunum the pain was referred to the upper abdomen 7 times, to the umbilical level 3 times and below that level only once; when the balloon was in the ileum the pain was referred to the lower half of the abdomen 11 times, to the umbilical level 5 times and above that level 4 times. When a circle with a radius of 10 cm. was drawn about the umbilicus it showed the point of referred pain from the jejunum to be outside the circle in 6 instances and inside it in 5; that from the ileum, to be outside the circle in 4 instances and inside in 16. Thus, in our subjects referred pain from the ileum was usually located below the umbilical level and within 10 cm. of the umbilicus. The location of the balloon in the abdomen had no relation to the point of referred pain. It is to be appreciated that this work refers only to pain

produced by distension of the bowel wall; the pain and tenderness produced by inflammation may have a different localization.

We have as yet made but a few bacteriological studies on the intestinal contents. In that the technique, however, affords an opportunity to enter the bowel quickly while the subject is fasting or at any desired time in the course of feeding experiments, it would seem to have an advantage over the method employed by Thompson and his coworkers (6). It obviously has many advantages over methods which involve the collection of specimens from fistulae, either in animals or man, in which skin contamination and a disturbed physiology of the bowel must be considered.

Finally, we wish to call attention to certain opportunities in the method for the study of persons with abdominal disease. We have not hesitated to intubate patients with unexplained abdominal pain, with abdominal distention, with ulcerative colitis, Addisonian anemia, common bile duct obstruction, a gastro-enterostomy and even one patient with intestinal obstruction from carcinoma of the cecum. In another patient with small intestinal polyps we were able to introduce a barium mixture into the affected small intestinal loop and so with the aid of the roentgenoscope bring clearly into view the fixed negative shadows. By placing the opening for aspiration at the distal end of the balloon in the patient with obstruction, pus was removed ahead of the balloon and peristaltic waves carried the apparatus into the upper ileum. A special modification of the tube has been designed by Abbott (15) for insertion into the stomach through the nose preoperatively and then at operation for the passage of its distal part through a gastro-enterostomy stoma; thus it permits subsequently the aspiration of stomach contents through one lumen and the administration of fluids directly into the jejunum through the other, and so obviates the necessity of post-operative intravenous injections. In one instance, in a very seriously ill patient, this modified tube was inserted at operation through a gastrostomy and then through a gastro-enterostomy stoma: it functioned satisfactorily for ten days and at autopsy no evidence of irritation about the stoma was demonstrable.

Thus, briefly, we have outlined certain investigations and therapeutic procedures carried out by our method of intubation and have indicated some further uses for the technique, in which, however, our experience is as yet limited. We hope the technique may prove useful to other investigators.

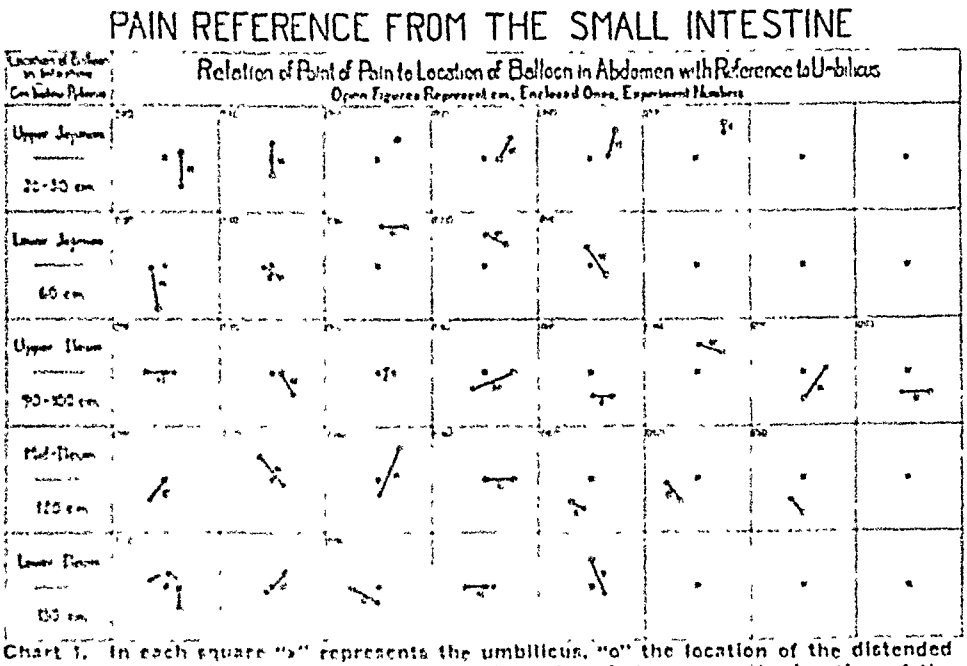

Chart 1. In each square "x" represents the umbilicus, "o" the location of the distended balloon in its relation to the umbilicus and the point of the arrow, the location of the pain. The figures at the middle of the straight lines represent the distance in cm. from the balloon to the point of pain.

DISCUSSION

DR. MAX EINHORN (New York City): I am very glad that Dr. Miller took pains to walk in the line which I tried to open up in 1910. Shortly after devising the tube, the duodenal tube, I tried right away first to have an obturator at the end of the tube and then an aspirating arrangement above it so that we should be able to examine, for instance, the duodenal contents separately and also to have X-ray pictures taken which Dr. Stewart at that time tried. I think it must have been 1912 or 1913, I do not know exactly.

Later on I made another attempt to investigate a small piece of the intestinal tract to localize it, having a three-cannula tube and obturator on the end and on the proximal side and in the middle a place for aspiration so that we could limit ourselves to a certain piece of the intestinal tract for separate investigation. I knew that certain experiments had been done but my intention was to give a method which could be practiced on patients.

Dr. McCafferty, who is still living, was the man on whom I have tried that method successfully. I was able to cut off the stomach, the duodenum, and localize a piece of the intestine so that the juice could be examined. I got the juice at that time. We could also localize, for instance, the papilla, cutting off a little ahead of the papilla and a few centimeters below.

But this instrument while it is all right to examine, interested me simply as a new way of doing something. However, I could not keep myself busy all the time with these experiments, or I would not have the time to treat patients. I had more important things to do than these experiments.

As to the intestinal tube, I tried right from the start to see how deep we could enter. There were all kinds of methods until I ultimately succeeded in having the tubes going down the entire intestinal tract. The tube which I found was the best for this purpose was an intestinal tube by means of which we can make the tube go into the caecum; but we can let it go through the entire intestinal tract. Here is a picture (showing printed pamphlet with illustration) of a patient who was treated at that time for ulcerative colitis. The tube went in further and we were able at that time to examine the intestinal contents of the descending colon.

Dr. Coleman and Dr. Thomson, a lady physician, helped me to carry out these investigations of the bacteria in the different regions of the intestine. This that I show you was published in about 1930, with the results of those examinations.

The difficulty is if we go with the tube away down into the intestine or the large bowel there is always contamination. It was necessary to seal up the tube first before we made the examination. We had to arrange for a collodion paraffin mixture which afterwards had to be tied up with a rubber band and then that tube could be sterilized. When we reached a certain depth in the intestine where we wanted to examine the bacteria it was opened and the intestinal contents aspirated. It would take too much time to go into the details of that.

I am very grateful to Dr. Miller that he took up these things again. If he says that it could go in in two or three hours and go away down, that I could not do. I think the physiological aspects point to the fact that we cannot do it as quickly as that. It would be an advantage, but I think if we want to examine things as they are we had better keep to the physiologic factor and act accordingly.

DR. LEWIS GREGORY COLE (New York City): I have just two points to make. One of them is merely of historical interest. We used a double tube with a balloon on the end to cause artificial dilitation of the duodenum and to wall of certain sections of the small intestinal tract. This was reported and illustrated in the Archives of Roentgenology in 1911.

The other point was a stunt that we used to enable the patient to swallow the tube with the collapsed balloon. We found that by sewing this balloon into an oyster and then having the patient swallow it, we often had little or no trouble.

DR. ANTON OELGOETZ (Columbus, Ohio, by invitation): I should like to emphasize the ingeniousness and practicability of this tube. We have been interested in obtaining the total pancreatic secretion. We attempted to get down to various levels of the bowel with single-lumen tubes, but until we had some correspondence with Dr. Abbott, we were unsuccessful. However, since then it has been very easy.

The first thing about this tube is that you can produce a temporary obstruction at any desired level of the bowel by inflating the balloon. We found the two-lumen tube the most useful. We only use the three-lumen tube to obtain secretions, simultaneously, from different levels of the bowel. This maneuver produced some very interesting results concerning digestion which we are going to report a little later.

This tube looks a trifle large. When you first look at it, it appears that the patient will have a terrifically difficult time swallowing it. But as a matter of fact, it is very easy. The smaller the diameter of the tube, the more difficult it is for the oesophagus and the bowel to grasp it by peristalsis. With this tube you can actually feel the tug of peristalsis. Most of our patients hardly gagged, whereas smaller tubes caused a lot of gagging.

We were especially interested in the rate of digestion of proteins and carbohydrates. We gave measured quantities of carbohydrates after passing the tube, and then withdrew secretions from various levels of the bowel at measured intervals. By starting at the ileum and withdrawing the tube a foot or so on successive days, we were able to determine how far down the bowel a given quantity of carbohydrate gets, before it is entirely digested, and how far down the resulting sugar gets before it is completely absorbed. We have done this same thing with measured quantities of protein.

In our experience this tube either goes through the pylorus very easily or it won't go through at all. Recently, we found it helpful to dip about two feet of the distal end of the tube into a thick solution of gelatine, which stiffens the tube. By the time the tube reaches the stomach, it softens, but still retains enough stiffness to enable one to push it through the pylorus.

Dr. Einhorn said that he was doubtful of the tube because he couldn't get it down. We had no difficulty in getting the tube to any desired level of the bowel, but at first, we were a little afraid of how to get it out again. When you get the tube far down in the bowel, as this picture showed, it appears as if the tube would act like a drawstring when you remove it, drawing the bowel into a knot and preventing removal of the tube. But it doesn't do this; it withdraws as easily as a duodenal tube. This tube is an ingenious method for finding out some hitherto unknown things about the intestinal tract at its different levels: pH at different levels and at different periods of the digestive cycle, bacterial content, enzyme concentration, where and when absorption takes place, and so forth.

DR. T. GRIER MILLER (Philadelphia, Pa., closing the discussion): I merely wish to thank these gentlemen for their kindness in discusing our paper. I really think it is hardly worth while at this time going into the part of the paper which the time limit did not permit me to present in full. I thank you very much.

The Components of the Gastric Secretion*

By

FRANKLIN HOLLANDER, Ph.D.
NEW YORK, NEW YORK

I HAVE been invited to speak to you today about the components of the gastric secretion, particularly with reference to my own contributions to the subject. Shortly after starting work in this field of investigation, I made a systematic search of its periodical literature. In the course of this task, three broad considerations came to assume dominant importance in my mind, and I should like to discuss them briefly at the outset.

First, the number of articles dealing more or less directly with this subject was tremendous. At the present time, my bibliography file contains well over a thousand such references — apart from an even greater number which deal with other aspects of gastric physiology. This literature is for the most part a confused mass of inadequate data, obtained by inaccurate analytical methods, and based on impure material such as stomach contents contaminated by saliva and duodenal fluids. Even material obtained in sham feeding or stomach pouch experiments was usually collected in such a way as to permit of contamination by blood from traumatized mucosa and by serous exudate from eroded areas around the mouth of the pouch. Although such quantitative studies ought to be carried out with physico-chemical precision, it seemed as if every investigator had made more or less the same observations in the same inaccurate way. As for the generalizations based on this work, it was amazing to see how frequently the conclusions were entirely unrelated logically to the observations from which they were supposed to have been deduced. Very often, the conclusions of several workers were diametrically opposite, although their data indicated no significant discrepancy. Such confusion might have been avoided effectively by statistical treatment of the data, but rigorous analyses of the observations were a rarity.

In the *second place*, and in consequence of this frequent lack of logical connection between data and conclusion, I found very few quantitative generalizations which were universally accepted. On the whole, opinion seemed to be divided into two camps. One of these supported the Pavlov theory,† which maintained that the acidity of gastric juice tends to be constant, and that the observed variations results from partial neutralization by mucus. The other group supported the Rosemann theory which maintained that the total chloride concentration rather than the acidity is the constant factor, because neutral chloride at fixed concentration is secreted as a precursor which undergoes partial hydrolysis to HCl. According to the latter view, increased intensity of stimulus results in an increased concentration of acid and a decreased concentration of neutral chloride. In spite of the sharp line which differentiates these mutually contradictory theories, neither had been proved conclusively in the course of a quarter of a century of research.

Finally, gastric juice was always thought of as if it were only a mixture of many chemical substances from a single source—the gastric mucosa. Although it was generally known that these substances came from several different kinds of secretory cells, very little consideration was given to their separate physiological origins. Investigators were concerned more with the chemistry of mixed gastric juice than with the chemistry of the individual secretions and their mutual interactions. During the last decade, however, emphasis has shifted perceptibly from the chemical entities to the physiological entities which constitute the mixed gastric secretion, and my own work is a manifestation of this different point of view. From this aspect, therefore, the components of the gastric secretion are defined as the individual fluids formed by at least four different types of secretory cell in the gastric mucosa.

From these considerations it was apparent that my own approach to the problem of the nature of the component secretions must be based on (1) a technique for collecting gastric juice of the very highest purity, (2) analytical methods of fairly high precision, (3) statistical treatment of the data wherever it is required, and above all (4) formulation of experiments with reference to the individual secretions and not to mixed gastric juice. Attention to these matters has already resulted in considerable clarification of the subject.

HISTORICAL CONSIDERATIONS

Before proceeding to the details of these results, however, I should like to review very briefly the major histological considerations of our subject. In spite of the variety of names associated with some of the gland cells, it is now generally accepted that the gastric mucosa contains four major types of secretory cell, which may occur in slightly modified form in different regions of the stomach. These cells and their secretory products are as follows: (1) The *mucous cells* of the surface epithelium, which give rise to viscous mucus and, on coagulation of the latter to the familiar strings and clots of mucin. (2) The *peptic cells* (also called *body chief, central* or *adelomorphous cells*) which secrete the enzymes. (3) The *parietal cells* (also known as *Belegzellen, acid, oxyntic*, and *delomorphous cells*) which contribute the HCl. (4) The *neck chief cells*, the product from which is unknown, though it may be a mucoid secretion according to Babkin (1931). The chemical composition of these secretions was entirely unknown, except for the one substance which served to characterize each of them. Also, apart from the unproved theories of Pavlov and Rosemann, nothing definite was known about the cellular source of the

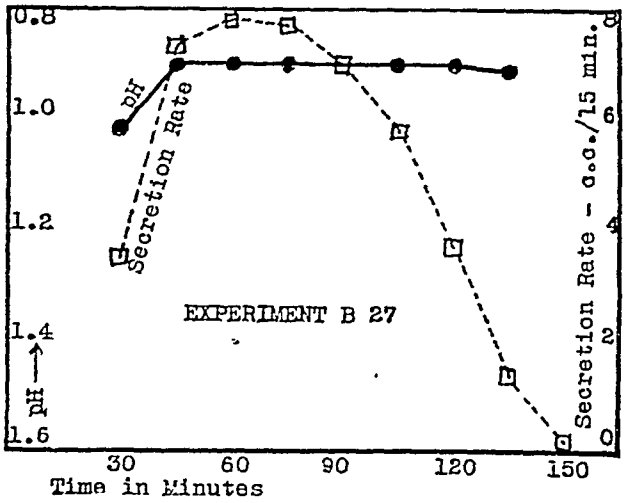

Fig. 1. Simultaneous rate and acidity (pH) curves, showing the attainment of constant acidity in spite of a marked rise and fall in rate of secretion. From a histamine experiment on a fundic pouch dog. (Hollander and Cowgill, 1931).

base, phosphate, protein buffer, etc., which are always present in gastric juice. Had it been possible to collect each individual secretion in the pure state by some micro-pipetting technique, such as that of Chambers for unicellular organisms or A. N. Richards for the kidney, the problem would have been relatively simple. Unfortunately, no such technique was possible and so it became necessary to develop an indirect approach in this search for the chemical composition of the individual secretions.

In keeping with the criticism which I made before regarding the use of impure gastric juice by other investigators, the first step in this work was the development of a technique for collecting gastric juice of the highest possible purity from Pavlov and Heidenhain pouch dogs; *i.e.*, juice which is free, not only of food, saliva, and regurgitated duodenal contents—such as is obtained in the ordinary gastric pouch technique—but which contains neither blood from injured mucosa, exudate from eroded skin and muscle, nor more than minimal amounts of mucin. Such a technique evolved in collaboration with Dr. G. R. Cowgill (Hollander and Cowgill, 1931), was based on the surgical development of a sphincter at the mouth of the pouch. By this method, the digestive fluid was retained in the pouch until it could be drawn off by temporary insertion of a small rubber catheter. Periodic removal of the accumulated juice prevented its leaking out continuously and thus eroding the abdominal wall surrounding the pouch opening. Furthermore, in collecting the juice for study, the sphincter obviated the use of hard rubber or metallic devices which cause considerable irritation and even injury to the pouch lining, thereby preventing contamination of the fluid with blood and excessive amounts of mucus. The gastric juice obtained by this technique was usually so clear and colorless that it might have been mistaken for ordinary distilled water. In addition to this collection technique, a special method was developed for analyzing the analytical data obtained from this material. This mathematical procedure involved the statistical treatment of a large series of samples of varying acidity; and it was based on a mathematical process known as "extrapolation," whereby it is possible under certain conditions to infer the composition of a sample of juice whose acidity value is higher or lower than any actually included in the original data.

Lack of time prevents my going into all the detailed results of this series of investigations, and so I shall touch merely on several of the high spots throughout the work.

(1) Previous investigators, almost without exception, had found that, in any one experiment, the acidity of gastric pouch juice rises and falls with the volume-rate of secretion, whether the stimulus be food or histamine. However, this parallelism of acidity and rate curves was cited by the proponents of both the Pavlov and Rosemann theories in support of their respective views. Under ordinary conditions of collecting the secretion, I also was able to confirm this observation, but when juice was collected by means of the sphincter technique I found that the parallelism no longer exists in the absence of irritating objects. This finding was verified independently by constructing a collecting device from a small, soft rubber catheter. With this contrivance and a relatively rapid flow of juice to lubricate the surface of contact between catheter and mucosa, it was found that the acidity rose to a maximum shortly after the beginning of an experiment and stayed there to the very end, even though the rate of secretion fell off in the usual way. Figure 1 is an excellent illustration of this independence of acidity and rate of flow of secretion, an observation which definitely proves the theory of Pavlov. The pH of this "constant acidity" juice was in the neighborhood of 0.9, or about 160 millimoles—which is numerically the same as clinical units (Hollander and Cowgill, 1931).

(2) Let us next consider the neutral chloride con-

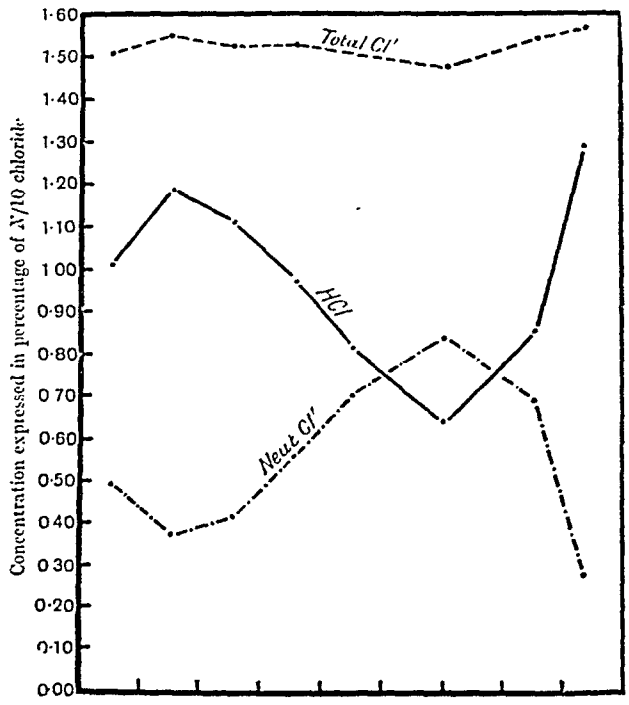

Fig. 1. Curves obtained from the secretion of an isolated gastric pouch in dog No. 1.

Fig. 2. Simultaneous acidity and neutral chloride curves, illustrating the inverse relation between these variables. (MacLean, Griffiths and Williams, 1928).

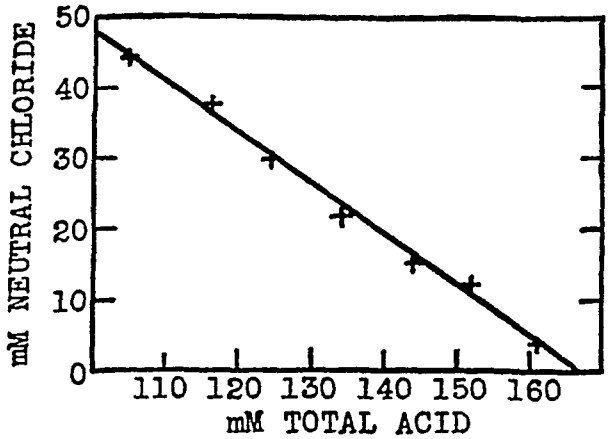

Fig. 3. Graph of neutral chloride and acidity data from 121 samples of pure mixed gastric secretion, treated statistically. The acidity intercept of this straight line, obtained by extrapolation, corresponds to pure parietal secretion with an acidity of 167 mm. and a neutral chloride concentration of zero. (Hollander, 1932).

tent of gastric juice, particularly in relation to its acidity. On this point also workers of the two schools were in agreement, *i.e.*, the concentration of neutral chloride always varies inversely with the HCl concentration. As the acidity rises, in any one experiment, the neutral chloride content falls, and as the acidity falls the other rises. This relation also was interpreted by each school to conform to its own views. A good illustration of this inverse relation, taken from a paper by MacLean, Griffiths, and Williams (1928) is given in Figure 2. My own observations have confirmed this fully. Indeed, in the case of the "constant acidity" juice, wherein the acidity values were as high as 150-160 mm., it frequently happened that the neutral chloride concentration was as low as 5-10 mm. This suggested that "constant acidity" juice might be almost, but not quite, pure parietal secretion; and that the latter, if it could be collected in a state of absolute purity, would be found to contain no neutral chloride whatever.

To test out this possibility, the mathematical technique referred to above was devised, and Figure 3 illustrates one of the experiments conducted for the purpose (Hollander, 1932). In this illustration over 120 samples of gastric juice of different acidities were collected from 5 different dogs. Each point on the graph represents an average of 10 to 20 of these samples, possessing nearly the same acidity; *i.e.*, its chloride and acidity values are averages of those for all the samples which it represents. Thus, instead of following the usual procedure and plotting both acidity and chloride values against the time of collection, as in Figure 2, I plotted the two concentrations directly against each other, as in Figure 3. The resulting graph was (statistically) a straight line, a result which was confirmed by several other series of observations. This straight line was then extended for a short distance beyond the last point, which corresponds to the specimens of "constant acidity" juice—a mathematical process known as *extrapolation*. In this case the line was extrapolated or extended downward until it crossed the acidity axis; the point of crossing is designated as the *acidity intercept* of the line. The theoretical specimen of gastric juice which corresponds to this intercept possesses a neutral chloride value of zero and an acidity of 167 mm. In the other experiments similar to this one, the acidity value of the intercept varied between 163 and 173 mm. These results were interpreted to mean that the gastric juice corresponding to these intercept values is the *ideally pure parietal secretion*, that this secretion is entirely free of neutral chloride, that its concentration of HCl is about 170 mm., and that "constant acidity" juice is this pure parietal fluid contaminated by small amounts of the other secretions from the gastric mucosa.

(3) Since the concentration of HCl in pure parietal secretion is *circa* 170 mm., and its neutral chloride content is zero, I next proceeded to investigate by a similar extrapolation technique, a number of the other chemical substances present in gastric juice (Hollander, 1934, a). Omitting all details of this study, it was found that the concentrations of combined acid, organic phosphorus, inorganic phosphate, and both inorganic and organic solids are all practically zero. Furthermore, it was shown that an HCl solution of *circa* 170 mm. concentration is isotonic with blood plasma, within the normal limits of experimental variation. Subsequently, Gilman and Cowgill (1933) showed that variations in blood osmotic pressure were actually paralleled by corresponding variations in osmotic pressure and chloride concentration of the gastric juice. In short, pure parietal secretion is an isotonic solution of practically pure hydrochloric acid. Its acid-base composition is represented by the first of the diagrams in Figure 4.

(4) Having shown that the parietal fluid contains only HCl, and that at a relatively constant concentration, the next problem was to determine the source of all the other chemical substances in mixed gastric juice and thus also the mechanism by which the ordinary variations in acid and neutral chloride concentration of pouch juice are brought about. In the case of the intact stomach, Boldyreff had advanced a theory based on the regurgitation of duodenal contents—an explanation which of late appears to be losing support among investigators. Since duodenal contents obviously cannot enter an isolated pouch, we are forced to infer that the effective agent in this situation is a non-acid fluid which is formed by the gastric mucosa itself. This fluid must supply the base which is present in the mixed secretion, in part as chloride and in part combined with the several buffer anions: phosphate, protein, and probably also bicar-

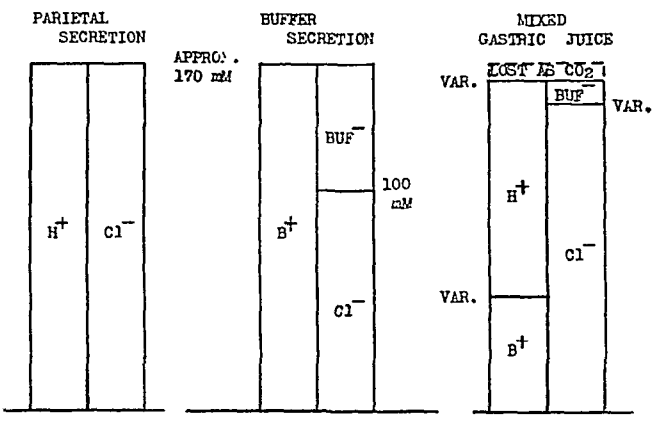

Fig. 4. Diagrams illustrating the acid-base composition of parietal secretion, buffer secretion and pure gastric juice formed by mixing the two secretions in variable proportions.

bonate which is lost as carbon dioxide on addition of acid.

The formation of such a non-acid fluid by both fundus and pyloric mucosa is well substantiated by the observations of Mitchell (1931), Martin (1932) and many others, and it seems very likely that this fluid is actually a specific buffer-containing secretion. As with the parietal secretion, no method was available for obtaining this fluid directly, but by means of the extrapolation method applied to a three coordinate system, and the data used for the previous study on the acid secretion, it was possible to arrive at a preliminary estimation of its chemical composition indirectly (Hollander, 1932). In this way it was suggested that the buffer secretion may be an isotonic mixture of neutral chloride and several buffer salts, and thus similar to blood plasma in its acid-base composition. The total concentration of base was placed around 170 mm., the chloride concentration about 100 mm., and the total buffer anion concentration about 70 mm.—as indicated in the second diagram in Figure 4. However, because of certain mathematical considerations, this extrapolation was not very reliable and the indicated composition was presented as a working hypothesis rather than an established fact. Subsequently, however, Wilhelmj and his associates (1934, 1935) reported that the chloride concentration of the non-acid secretion from dogs' pyloric and whole stomach pouches is 101 mm. on the average; its average concentration of buffer anion is 40 mm., but values as high as 80 and 90 were obtained. Also, Bolton and Goodhart (1931) reported a minimum chloride value of 99 mm. for the non-acid component from the fundus juice of cats. This evidence lends ample support to my earlier prediction regarding the similarity in acid-base composition between the buffer secretion and the blood plasma, but much work remains to be done before this similarity is established conclusively.

It follows from the foregoing, therefore, that in any sample of mixed gastric juice (see the third diagram in figure IV) the sum of the concentrations of total base (B+) and total acid (H+) will be equal to the sum of the concentrations of chloride (Cl—) and buffer anion (BUF—). Both of these sums will be less than the isotonic concentration (*circa* 170 mm.) by an amount equal to the amount of acid which was lost as H_2CO_3 or CO_2. In no case can the chloride concentration in gastric juice fall below that of the buffer secretion, about 100 mm., unless it be through the agency of some other fluid. In any particular sample of gastric juice, the relative values for the concentrations of HCl and neutral chloride will depend on the relative volumes of the parietal and buffer secretions. It must be added, however, that only part of the neutral chloride content of mixed gastric secretion arises by neutralization of the acid and the buffer salts; the larger portion exists as such in the non-acid fluid. Also, in addition to their chemical interaction, these two secretions exert a mutual diluting effect which serves further to reduce the concentrations of their respective constituents.

A final word concerning the source of this buffer-containing fluid. Originally, Pavlov postulated that ordinary deviations from constant acidity were the result of admixture of mucus secretion. In the absence of evidence to the contrary, this viscous fluid must still be admitted as a possible source of the buffer salts. However, my own experience has indicated that variations in the acidity of pouch juice may occur in the almost complete absence of mucin and therefore of the viscous mucous secretion. For this reason, it seems much more likely that the major part of the buffer-containing fluid arises as an independent secretion, which is identical with the dilution secretion (Verdünnungs-sekretion) of previous investigators. It is even possible that the mucoid secretion of Babkin (*vide supra*) and his associates, Webster and Komarov, (1932) is likewise identical with these, and that the source of the buffer secretion is the neck chief cells of the gastric tubules.

To summarize: Pure gastric juice is a mixture of at least four independent secretions from the gastric glands. As yet we know nothing about the chemical composition of the secretions from the peptic and mucous cells. The parietal secretion has been shown to be an isotonic solution of practically pure hydrochloric acid, thus finally resolving the old Pavlov-Rosemann controversy regarding the constancy of the gastric acidity in favor of the former. This is the first of the digestive secretions for which the chemical composition has been established. The normal variations in the acid and neutral chloride concentrations of pouch juice are caused by a buffer-containing secretion which acts by both neutralization and dilution of the parietal fluid. It is suggested that the chemical composition of this buffer secretion is probably similar to that of blood plasma, so far as its inorganic constituents are concerned. Furthermore, it is probably identical with the dilution secretion of other investigators, and perhaps also with the mucoid secretion of Babkin and his associates. Finally, I believe that we already have sufficient evidence to show that the buffer secretion plays a major role as an intragastric agent in the normal control of gastric acidity—more important even than duodenal regurgitation as an extragastric agent. As such, this secretion is of tremendous importance to clinicians and physiologists alike, and it deserves extensive investigation by both.

DISCUSSION

DR. WALTER C. ALVAREZ (Rochester, Minnesota): I do not feel quite qualified to discuss such a technical chemical subject with my poor knowledge of chemistry. But, I will say this as one interested in physiology, it seemed to me for years that we were floundering around, many of us trying to learn something about gastric secretion, using juice from the stomachs of human beings, mixed with food. God knows gastric juice is complicated enough without adding mixtures of food and whatnot to it.

Imagine that this arm and hand of mine represent a gastric gland. Here near the bottom are the chief cells. Nearer the mouth of the gland are the mucoid cells; outside of these cells are the parietal cells. As a physiologist,

I would like to know what are the secretions of these several cells.

In the gastric juice one finds acid, pepsin, mucous, and other substances. Where did they come from? Which of the cells produced which ones of the different constituents?

For years it seemed to me that we physicians were floundering around in a morass of ignorance because we were ignoring the need for answering these important and basic questions. Then, one day I happened to pick up the Journal of Biologic Chemistry for January, 1934. There I found an article by a man whom I did not know. In that article there was light on the subject of gastric acidity and plenty of it. At there was the beginning of an answer to the questions that had been in my mind.

As I commonly do when a man's writings greatly please me, I promptly made a pilgrimage to see him and found him to be a real fellow. His work and his thoughts expressed in letters have been a big stimulus to me ever since. I wish he could get back to this work on gastric juice because he has the mental equipment and the technical training with which to tackle the problems as I think they should be tackled.

Now, why am I so interested in learning exact details as to the secretion of the gastric juice? Because, as someone who has to treat peptic ulcer, I want to learn how to cut down the secretion of acid. How happy we physicians would be if we could produce even temporarily hypo or anacidity in patients with ulcer; then many of our troubles would be over.

We want to throw a monkey wrench into the machinery of acid formation, but where are we to put it until we know every stage in the production of the acid; until we know the chemical processes that go on, and how those processes are linked up with varying conditions in the blood, such as the amount of CO_2, chlorides, etc. When we know all these details then we may see a place in which the insertion of a small monkey wrench can have a big effect in decreasing the secretion of gastric acid.

DR. FRANKLIN HOLLANDER (closing the discussion): There is one particular point which I should like to emphasize in closing. The idea of a non-acid gastric secretion, of course, is far from being new. However, as this concept has usually been advanced, it involves a secretion which contains only neutral chlorides but no buffer salts; that is, a fluid which causes the ordinary variations in gastric acidity solely by a process of dilution. Now, the chief objection to this theory which has been raised in the past is this, that there is as yet no evidence to indicate that such a fluid can be secreted in sufficient quantity to be effective as an agent in the intragastric control of the acidity. I think the present is an opportune time to answer this argument.

In the first place, proponents of an extra-gastric mechanism of acidity regulation have sponsored Boldyreff's theory of duodenal regurgitation. But no such mechanism can operate in the isolated stomach pouch. Nevertheless, quantitative variations in acidity and neutral chloride content can be observed to practically the same extent in pouches as in intact stomachs. It follows, therefore, that since such reductions in acidity can occur in the pouch without the aid of an extra-gastric mechanism, there is no need for our invoking one in the case of the entire unoperated stomach. In other words, there must be some intragastric secretory agent which is elaborated in sufficient quantity to act in this way.

In the second place, the non-acid secretion which I have described today differs from the older notion of a dilution secretion in this respect, that it functions as an agent of acidity regulation, not only by dilution, but also by a process of neutralization. Consequently, comparing it with an equal volume of the simple dilution secretion, the reduction in acidity effected by the former will be considerably greater than that caused by dilution alone. In other words, the buffer secretion is more efficient and therefore even less of it is required to regulate the acidity than of the other.

Of course, complete refutation of all arguments against the existence of this buffer secretion must rest ultimately on its actual isolation and our learning more about it, particularly the stimulatory mechanism by which it is formed in the normal course of digestion.

Gastric Secretory Behavior in Chronic Gastritis*

By

J. F. MONAGHAN, M.D., H. L. BOCKUS, M.D.

K. KORNBLUM, M.D.

PHILADELPHIA, PENNSYLVANIA

and

G. R. MOFFITT

HARRISBURG, PENNSYLVANIA

THERE are many who feel with Hurst, Faber and Konjetzny, Henning and Schindler that gastritis is the most common stomach disorder. Great difficulties are encountered when an effort is made to diagnose or classify cases of gastritis, which have not been proved by gross and microscopic study of operation-room material. Only those cases associated with ulcer and cancer have had world-wide scrutiny and even in these the assumption of a primary gastritis has not been proved.† Stomachs examined at autopsy, which have not been treated immediately after death by the Faber formalin method, are of little value for pathological study, and that method is little used. There remains that large group of patients upon whom a tentative diagnosis of gastritis is entertained whose stomachs should not be removed by the surgeon and who do not go to necropsy. A clinical suspicion of gastritis, based upon the existence of possible etiological factors, can only be confirmed by analysis of the

*Delivered at the Thirty-ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936.
Approved by the Committee on Publications.

†Cases of proven gastritis in association with ulcer and cancer have purposely been omitted. The secretory behavior of this group will be the subject of a later paper.

From the Gastro-enterological Clinic, University of Pennsylvania Graduate School of Medicine.

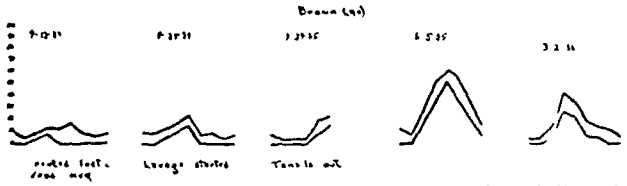

Fig. 1, Case 1. Marked improvement in gastric acidity following treatment for lues, gastric lavage and tonsillectomy.

stomach contents, the gastroscope and study of the mucosal pattern by X-ray. Unfortunately interpretation based upon any of these methods is subject to considerable error. There is great need for standardization and comparisons of the methods of diagnosis in cases followed for long periods. It is for this reason that we offer no apology for presenting a group of cases, in many of which the diagnosis of gastritis is not surely established, for critical review of the secretory findings. Most cases presented have been examined gastroscopically, and unquestionably in the light of our present knowledge many would make an unequivocal diagnosis of gastritis. We purposely omit the gastroscopic findings until we feel, with our endoscopist, Doctor Tucker, more certain of the gastroscopic diagnosis. X-ray studies of the mucosal pattern have been routinely carried out and indications of gastritis in the light of more recent work were frequently present, although they were not always pathognomonic.

The cases share commonly evidences of a "dirty stomach," *i.e.*, excessive gastric sediment in the fasting and lavaged stomach which microscopically showed large amounts of mucus, pus, bacteria and exfoliated gastric epithelium. The residua were always examined by one of us and not by inexperienced technicians. We realize, of course, that cases of gastritis may show no evidence of exudation, desquamation and infection by this method and likewise that the personal equation in the interpretation of the findings is considerable.

In 18 cases special tissue block sections were prepared from the gastric sediment removed through the stomach tube by the method of Moffitt and the material stained, sectioned and studied in the same manner as pathological tissue sections. In only three of them, gastric tissue fragments were found which afforded an opportunity for detailed study. Although only 16 per cent of the cases examined in this way yielded satisfactory material for study, we feel that the method may prove a valuable adjunct in the diagnosis of gastritis. (Foot Note).

Foot Note *Technique of sectioning sediment of gastric washings* After recording the gross description and amount of the fluid a small quantity is placed upon a slide and observed to determine whether there is enough mucus or other viscid matter present to allow the sediment to form the necessary firm mass when acted upon by formaldehyde and also to obtain information in regard to the character of the sediment, whether mucoid, hemorrhagic, biliary, amorphous or granular, for it is necessary, in case of the latter two, to add a little gelatin to hold the amorphous or granular matter in a mass.

One drop of ten per cent gelatin solution is added to each two cubic centimeters of the fluid

The fluid is then centrifuged at a high rate of speed (about 4000 revolutions per minute) for one-half hour. This causes the sediment to be tightly packed in the bottom of the tube The supernatent fluid is discarded and the tube filled with 6% formaldehyde (15% formaline).

A narrow, flat, flexible applicator is passed about the plug of sediment to loosen it from the glass so that the hardening action of the formaldehyde will begin promptly.

The formaldehyde is allowed to act upon the sediment for a week being changed at the end of twenty-four hours and once or twice later

The hardened sediment caked in the bottom of the tube is worked loose by means of the metal applicator taking care not to break it. It is then treated as though it were a section of tissue—passed through the alcohols, ether and absolute alcohol, thin celloidin, thick celloidin, mounted in celloidin, sectioned and stained with haematoxylin and eosin.

Celloidin is used in preference to paraffin as granular sediments generally drop out during sectioning when the latter is used

Any floating mucoid masses which do not centrifuge to the bottom of the tube—and these are quite frequently encountered—are treated just as are the hardened sediment masses

The group of cases selected permit a study of secretory behavior over long periods or illustrate changes in secretory status of particular interest. A lengthy period of observation in a few cases properly followed up should prove of more value than a much larger group followed for a briefer period of time. All of the secretory data have been obtained by the ordinary two-hour fractional gastric analysis, using the bread and water meal with or without histamine.

GROUP I—CASES OF POSSIBLE GASTRITIS WITH REDUCED OR ABSENT ACIDITY SHOWING INCREASED ACIDITY AFTER THERAPY

Practically all observers are agreed that there is a tendency toward reduction in gastric secretion as measured by gastric analysis in chronic progressive gastritis. Hurst attributes the reduced acidity to degenerative changes in the oxyntic cells, obstruction to the intracellular canaliculi by swollen cells and an excessive secretion of mucus which neutralizes the acid to a slight extent and blocks up the mouths of the secreting tubules. Henning found either hypo or anacidity in 68 per cent of stomachs showing evidences of chronic gastritis by gastroscopy. Faber feels that the development of achlorhydria is primarily dependent upon the gastritis per se and may develop in any stomach regardless of the previous acid level. Hurst favors a constitutional hypo-acid diathesis as an impor-

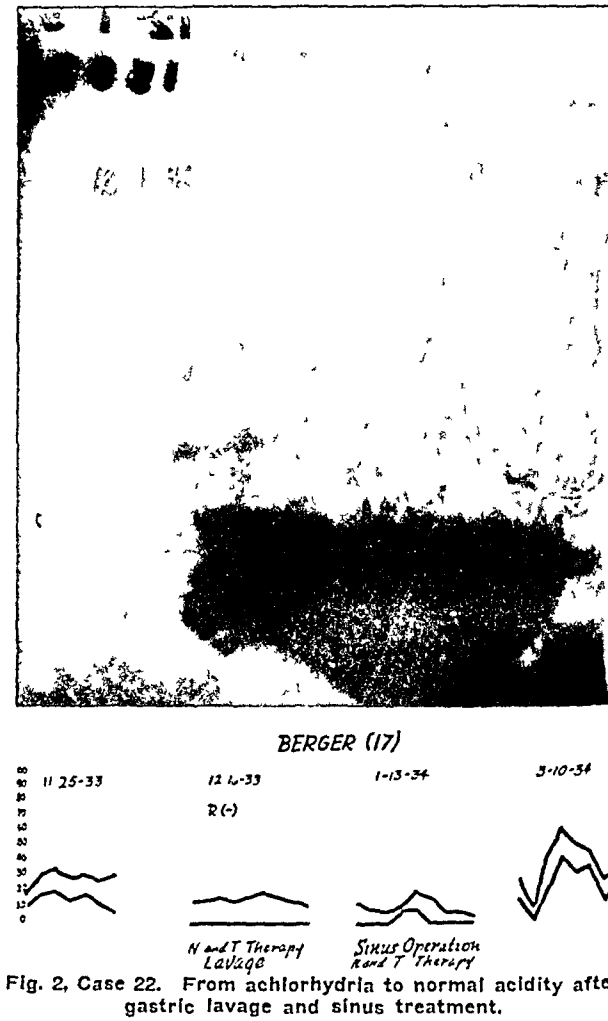

Fig. 2, Case 22. From achlorhydria to normal acidity after gastric lavage and sinus treatment.

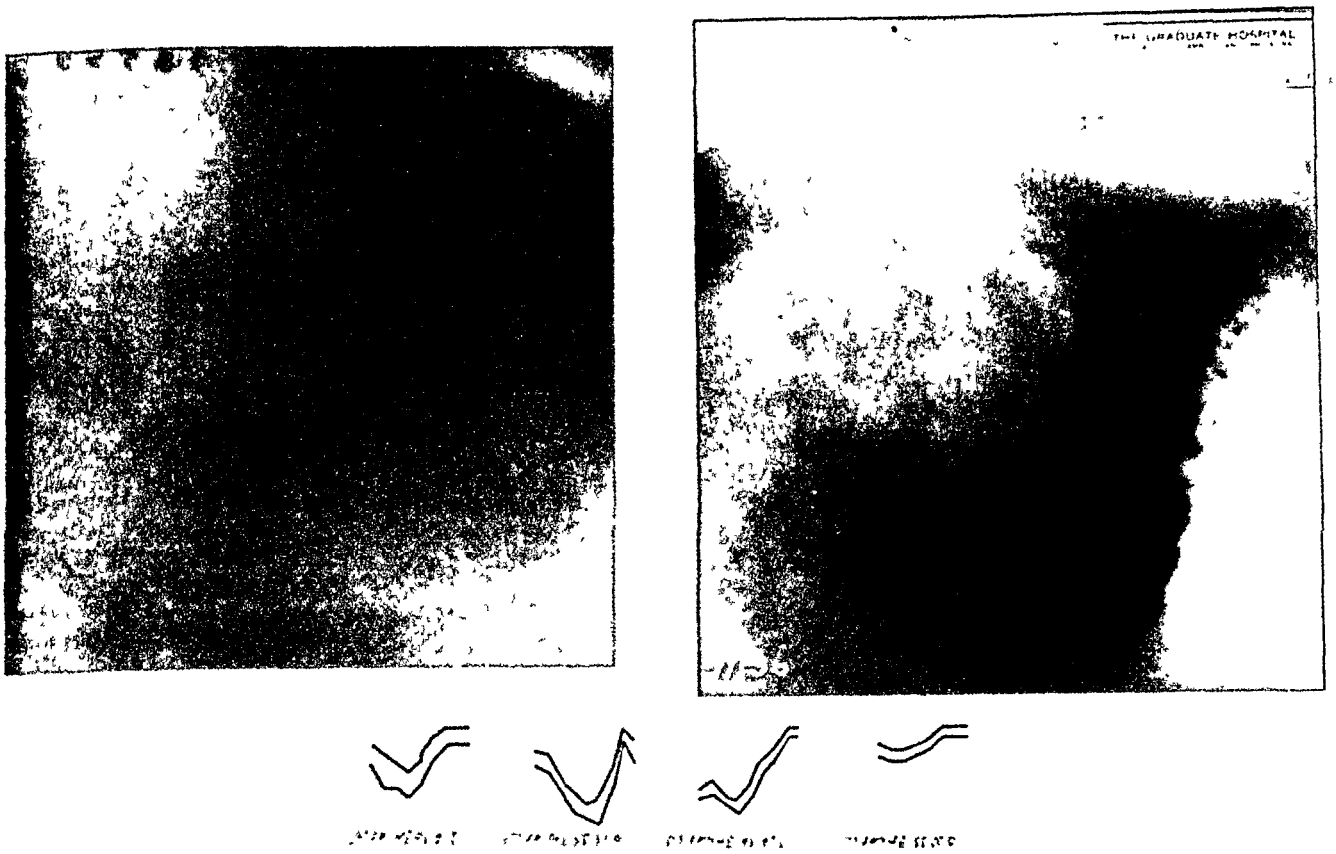

Fig. 3, Case 23. Dilated stomach gradually reduced in size with hypochlorydria changing to normal acidity during treatment for gastritis with lavage.

tant conditioning influence. He assumes that very near all individuals with the constitutional "hypo-acid diathesis" and a few with normal acid eventually develop achlorhydria as a result of gastritis, claiming that the "inborn" hypochlorhydria renders their stomach mucosa more liable to injury and permanent damage following insult.

Hurst claims to have brought about a return of acid in 80 per cent of his cases of achlorhydria by treatment directed toward gastritis. A group of cases has been selected to illustrate improvement in the secretory level following various therapeutic agents.

Case 1, V. B., a colored female, 39 years of age, was admitted September 12, 1933, because of early postprandial epigastric distress of two years' duration. Her Wassermann had recently become negative after treatment for a gumma of the sternum. Pertinent findings were a gastritis, right hypertension, obesity, mild hypothyroidism, diseased tonsils and dental caries. The sediment from the fasting and lavaged stomach suggested mucosal inflammation. The X-ray evidence of gastritis was not convincing. The acid curves from September, 1933, to January, 1935, showed an extreme hypochlorhydria. A normal acidity appeared in June, 1935, after 2 years of treatment, including antiluetic therapy from April, 1933, to June, 1934, gastritis management with frequent therapeutic lavage starting in August, 1934, and tonsillectomy in January, 1935, (Fig. 1).

Case 22, S. B., a white girl, 17 years old, showed a change in secretory status from an apparent achylia (without histamine) to normal acidity within 3 months after sinus drainage and nose and throat treatments (Fig. 2) for maxillary sinusitis and chronic ethmoiditis with postnasal discharge. Nausea, early postprandial distress, and anorexia disappeared with the return of acid and the patient gained in weight. The accompanying illustration shows an unusually smooth mucosal pattern. The gastric sediment was rich in cells, mucus and bacteria.

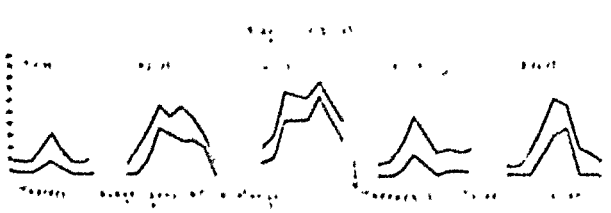

Fig. 4, Case 16. From hypochlorhydria to hyperacidity after gastric lavage and extraction of teeth with return to hypochlorhydria after discontinuing "gastritis" therapy.

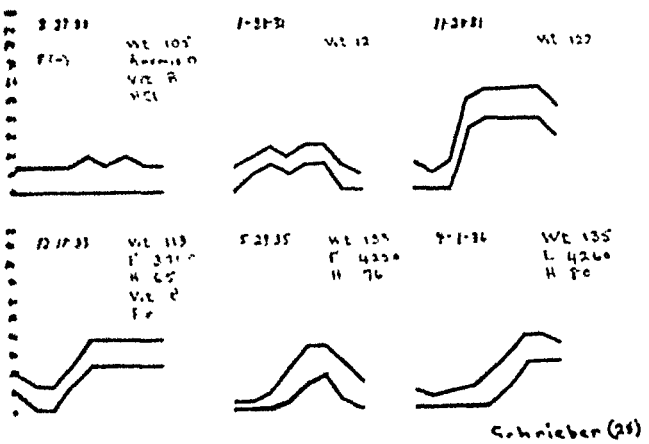

Fig. 5, Case 6. Achlorhydria to normal acidity with vitamine "B" and hydrochloric acid. Therapy discontinued with subsequent anemia and hypochlorhydria.

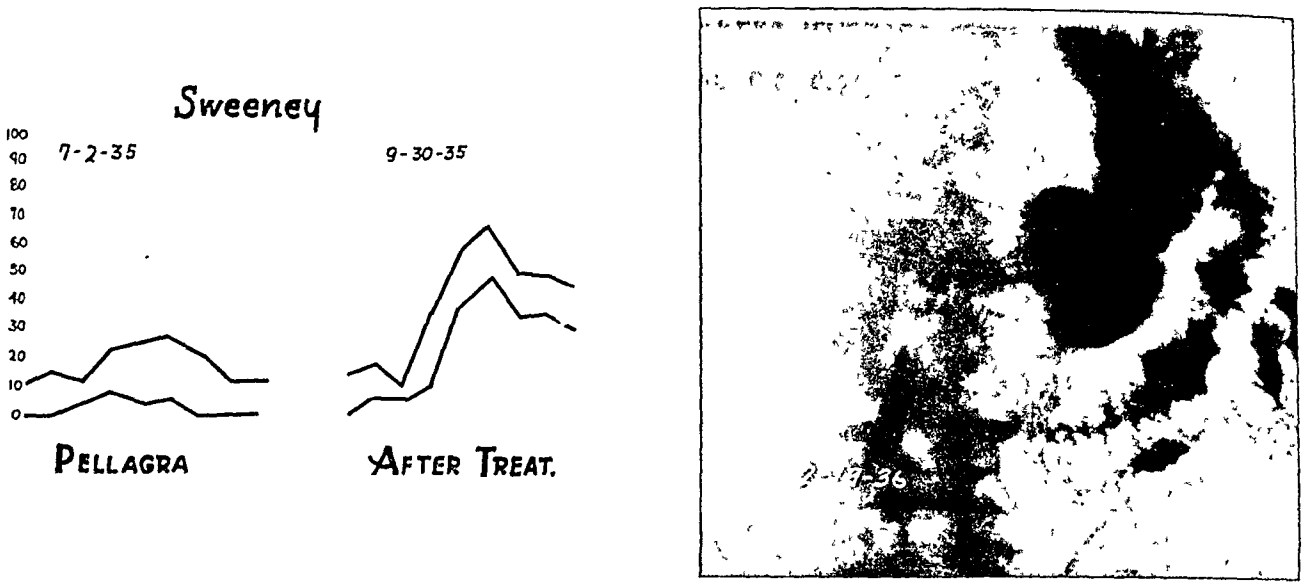

Fig. 6, Case 17. Hypochlorhydria to normal acidity in a pellagrin on vitamine "B."

Case 23, M. B., a colored female, 34 years of age, showed a tremendously dilated stomach without ascertainable cause and hypochlorhydria in June, 1933. Bouts of nausea and postprandial fullness had been recurring for several years. Studies revealed hypothyroidism and hypertension. Therapeutic lavage was given from April to September, 1933. The stomach gradually decreased in size and the gastric analysis showed a hyperacidity in July, 1934, (Fig. 3). Evidence of gastritis was suggested by examination of the stomach contents and study of the mucosal pattern.

Case 15, A. M., an Italian female of 21 years, showed an extreme hypochlorhydria in July, 1933. The acidity gradually mounted to a slight hyperacidity in 4 months (Fig. 4) following therapeutic gastric lavage and extraction of abscessed teeth. Re-examination after a year's absence from the clinic showed a lowering of acidity which started to mount a second time upon instituting glandular therapy for hypothyroidism. X-ray evidence of gastritis was lacking but the stomach residua were suggestive.

Case 6, H. S., an asthenic, under-nourished nurse of 25 years, shows an interesting type of secretory behavior during a six-year period (Fig. 5). In March, 1930, there was an apparent achylia (no histamine), the gastric residue containing many pus cells and phagocytes. The stomach films were unsatisfactory. Vitamine B, hydrochloric acid and a high caloric diet were followed by hypochlorhydria in January, 1931, and normal acidity in November, 1931. At this time the amount of cellular and mucoid sediment had increased. In December, 1933, after cessation of therapy, the acid curve was lower and a moderate anemia developed. In spite of iron and vitamine B with improvement in the blood-count, the acid curve was

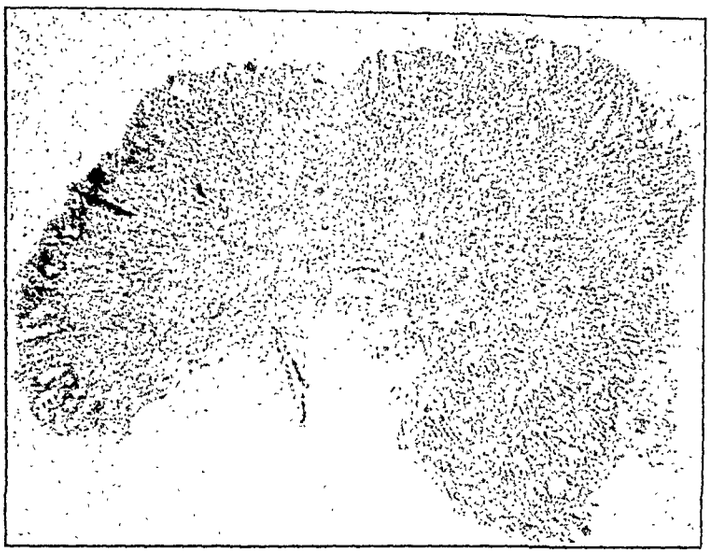

Fig. 9A, Case 14. Fragment of gastric mucosa (X32) aspirated through open tube gastroscope.

still lower in May, 1935, and remained low. X-ray in April, 1936, was very suggestive of gastritis. Etiological factors may have been diseased tonsils, frequent chronic "colds" and chronic constipation. The patient gained 30 pounds in weight during the six-year period.

Case 17, D. S., a typical alcoholic pellagrin, over 50 years of age, with evidence of multiple type of deficiency disorder is included to illustrate the return of gastric acidity to normal after administration of vitamin B. Liver was purposely withheld (Fig. 6).

Case 25, M. L., Jewish male, 22 years old, illustrates an improvement in secretory status following splenectomy for typical Banti's disease. The gastric analysis showed an apparent (no histamine) achylia previous to splenectomy (Fig. 7), which occurred March 24, 1933. Two months later gastric rennet was present but no acid after histamine injection. Tri-weekly gastric lavage was given from May until August, 1933. In early July, acid appeared only after histamine injection. In June, 1934, the gastric secretory status was the same (achlorhydria with ordinary meal and hypochlorhydria after histamine). From June, 1934, to May, 1935, bi-weekly gastric lavage was carried out. From February until October, 1935, the stomach secreted acid without histamine. The secretory status improved from an apparent achylia to a true hypochlorhydria after splenectomy.

Case 14, K. D., an Italian female, 34 years of age, is of

Fig. 9B, Case 14. High power (X200) of 9A showing signs of inflammation and degeneration of gastric mucosa.

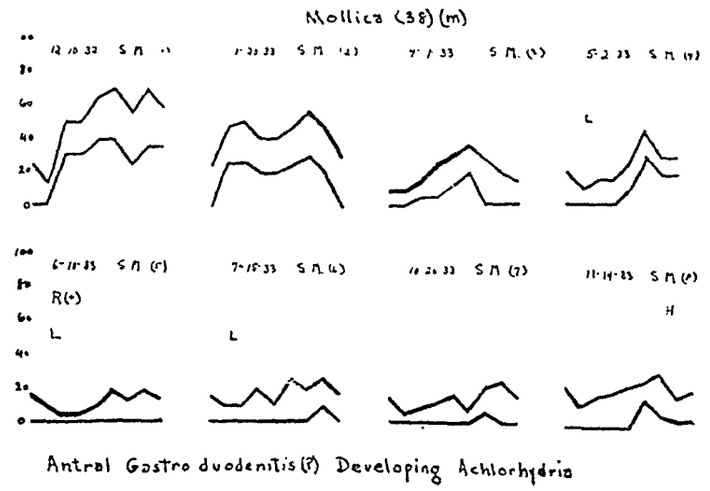

Fig. 10, Case 13. Probable gastro-duodenitis with normal acidity developing achlorhydria in spite of "gastritis" therapy.

special interest because of cardiospasm of four years duration with dilatation of the esophagus. She consumed alcohol in moderate amounts and had several abscessed teeth. The stomach films suggested a possible gastritis of the proximal one-third of the stomach. Gastric acidity changed from a slight hypochlorhydria to normal acidity during one year (Fig. 8). The gastric sediment showed excessive amounts of mucus, pus cells and bacteria. Material, aspirated through the open tube gastroscope and prepared by the method of Moffitt, yielded tissue fragments of sufficient size and character to justify a diagnosis of gastritis (Fig. 9).

Histological Description.—The section shows three fragments of gastric mucosa and hyaline blood clot. The surface epithelium of the mucosa is missing, being covered by a fibrinous exudate in some places and in others a thin cuticular border. The alveolae are dilated by retained mucus (goblet cells) and degenerated and their lumena filled with protoplasmic-cell remnants and mucus. Many of the nuclei at the bases of these cells have survived. The cells of the neck portions of the glands show no advanced changes. In the deeper portions of the glands, the cells of some are in fairly good condition while in others various degrees of cloudy swelling or albumenoid degeneration are observed. The chief cells are more affected than the parietal cells. In some areas the glands are fragmented and scattered about in the tunica propria. The tunica

propria or corium of the mucosa is degenerated in places and the seat of old hemorrhages. In other places it is densely infiltrated with wandering cells, plasmacytes greatly predominating instead of the lymphocytes which are normally present in this fibroreticular tissue.

Comment: It is conceivable that the cardiospasm may have resulted from an infiltration of the nerve plexus in the terminal esophagus secondary to an esophagogastritis in much the same way which Hurst has accounted for some cases of "achalasia" of the cardia from infiltration of Auerbach's plexus in syphilis. The patient did not have tuberculosis or syphilis or any appreciable anemia. Two other cases of cardiospasm are being followed with clinical and laboratory evidences of gastritis.

DISCUSSION

The diagnosis of gastritis in this group, which share commonly an improvement in secretory status, is largely dependent upon examinations of the gastric residue and lavage fluid. We do not agree with Hurst that excessive mucus alone is pathognomonic of gastritis any more than we would designate all cases "colitis" because of mucus in the colon. Indeed caution is necessary in the interpretation of microscopic evidence of inflammation and desquamation in terms of gastritis unless the sediment is excessive and not due to oral or duodenal influx. X-ray evidence of gastritis was suggestive in cases 17, 22, 23, 6 and 14. Needless to say, many cases of proved gastritis may show little by ordinary X-ray examination.

These cases illustrate the various agents which may be responsible for improvement in the level of gastric acidity. Gastric lavage, two or three times weekly, was used in 4 cases. Sinus drainage and treatment were followed by a change from apparent achylia to normal acidity in one case. A cleaning-up of dental foci may have had a beneficial effect in one and tonsillectomy in another. In 2 cases improvement in the secretory status followed the administration of vitamine B. One was an alcoholic pellagrin. The other patient gradually showed a return to normal acidity from an apparent achylia while taking yeast and hydrochloric acid. This apparent response to vitamin B is of interest in view of the recent inability of Alvarez *et al* to reduce gastric acidity in normal people by deprivation of vitamin B_1 for six weeks. It would be interesting to repeat their experiments on patients with gastritis. It is possible that excessive amounts of vitamin B_1 are essential to the maintenance of acid in these cases. The improvement in secretion following splenectomy for Banti's disease in one patient and the probable benefit from antiluetic treatment in another is readily understood.

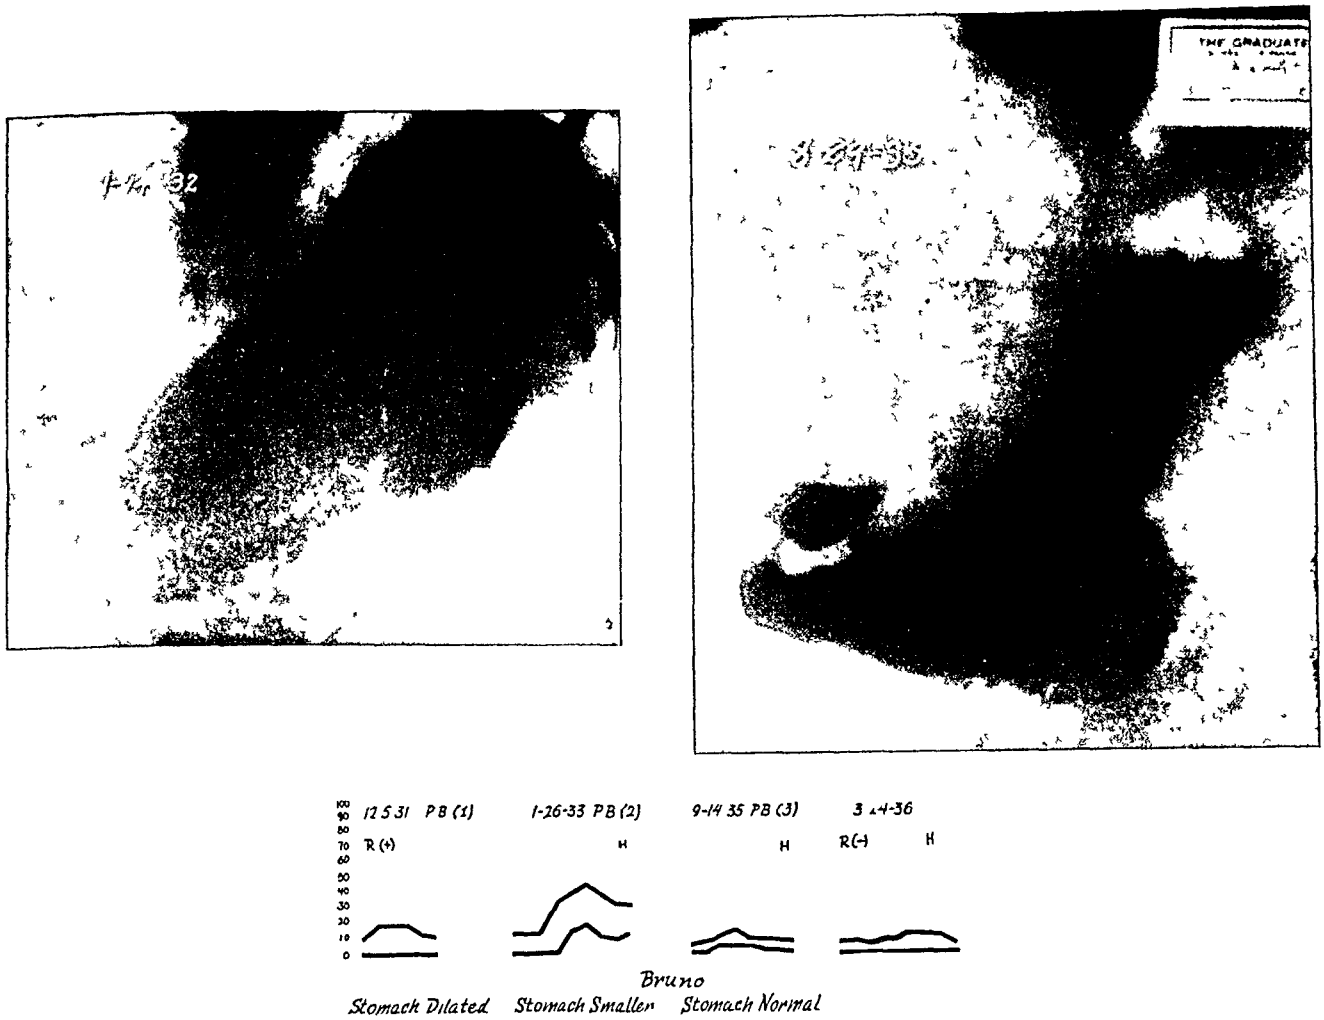

Fig. 13, Case 3. Dilated stomach with achlorhydria in man of 78, suspected of carcinoma in 1931. Showing gradual return of stomach to normal size and development of histamine refractory achylia during 4½ years.

The most significant finding in this group of patients is their youth. All were under thirty-five except the alcoholic pellagrin and the leutic patient. In 1932, we reported 65 cases of achlorhydria by the ordinary two-hour Rehfuss fractional gastric analysis, which were subsequently tested with histamine Only five of this group under age thirty showed achlorhydria after the ordinary analysis and only two of the five had a true achylia gastrica after histamine injection. Three cases in this present series with apparent achlorhydria were under age 26. None was proved to be truly achylic and all responded to treatment. This reflects our usual experience Absence of both acid and enzyme after histamine injection is exceedingly rare under age 30 and apparent achylics (without histamine) under age 30 usually show a secretory response to histamine and a clinical response to gastritis treatment. If a diathesis for achlorhydria exists, all evidence certainly indicates that it does not often become manifest until age forty or later. Experience with achlorhydria and hypochlorhydria in youth indicates that attention paid to the ablation of foci in the nose and throat and mouth, stomach rest, lavage, vitamine B, and attention to other etiological factors which may be responsible for gastritis, offers an excellent chance of improvement in the secretory status and clinical condition of the patient.

GROUP II—CASES OF POSSIBLE GASTRITIS WITH LOW OR DIMINISHING GASTRIC SECRETION

For purposes of comparison, it should be of interest to study a group of patients without true achylia, who failed to show improvement in gastric secretion on appropriate treatment.

Normal acid to hypochlorhydria. Case 13, S. M., an Italian male, 38 years of age, complained of early morning and early postprandial epigastric distress for two years. He gave a history of malaria in 1911 and of gross dietary indiscretions and showed marked dental sepsis. The fasting gastric contents suggested diffuse mucosal inflammation with microscopic food remnants, and the roentgen diagnosis was gastro-duodenitis. . Normal gastric acidity in December, 1932, was gradually replaced by an extreme hypochlorhydria during the next year (Fig. 10) in spite of symptomatic relief by occasional gastric lavage, smooth diet and hydrochloric acid.

Case 9, J. L , white male, 38 years of age, gave a history of nausea, vomiting and epigastric distress and possibly hematemesis at irregular intervals for 5 years. The past history revealed attacks of scarlet fever, influenza and quinsy Apical dental abscesses, pyorrhea and diseased tonsils were present. The gastric residua were suggestive of gastritis and slight delay in stomach emptying. X-ray pointed toward a prolapsus of the gastric mucosa through the pylorus A progressive depression of the secretion

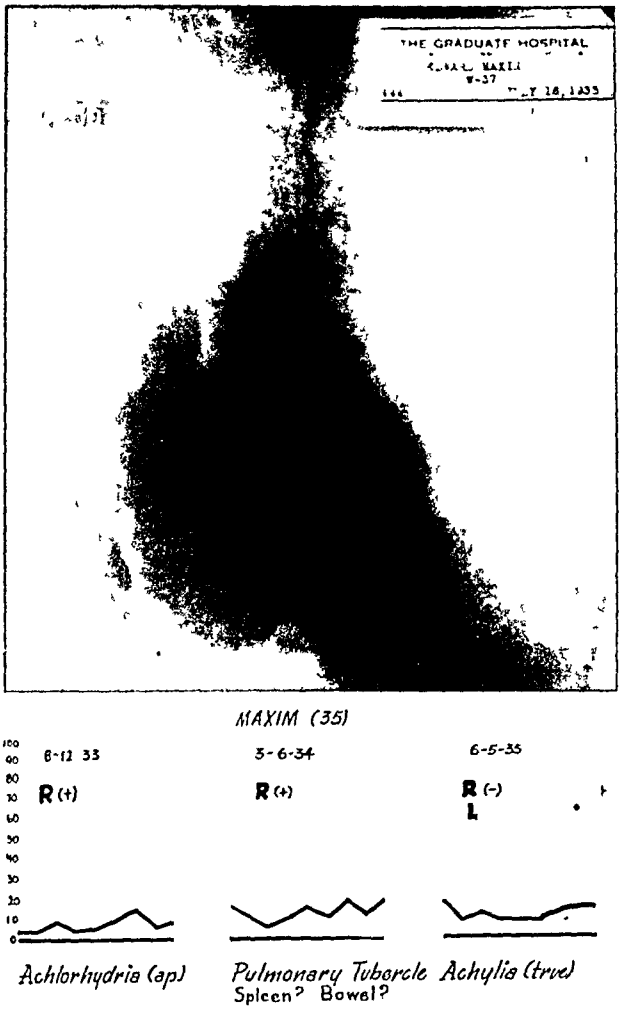

Fig. 14, Case 31. Pulmonary tuberculosis with X-ray evidence suggestive of gastritis with an apparent achlorhydria changing to histamine refractory achylia.

curve occurred between February, 1932, and August, 1934, (Fig. 11) in spite of a modified ulcer regimen and removal of dental foci.

Comment: These two cases have in common the factor of age, normal acidity on admission, slight delay in stomach emptying, excessive mucoid and cellular gastric sediment, the absence of a circumscribed gastric or duodenal lesion and symptomatic relief on a gastritis regimen. Both exhibited a striking and consistent trend downward to the point of definite hypochlorhydria

Gastrectasia with hypochlorhydria. Case 10, D. V., a colored female, 33 years of age, appeared in August, 1934,

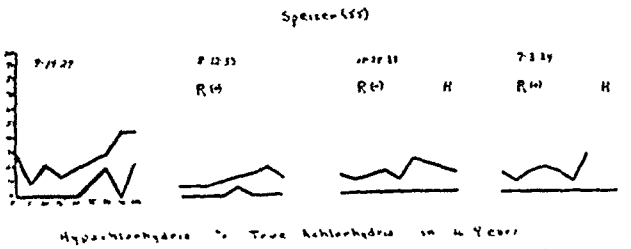

Fig. 15, Case 27. Hypochlorhydria to histamine refractory achylia in 4 years with return of enzyme after histamine 8 months later.

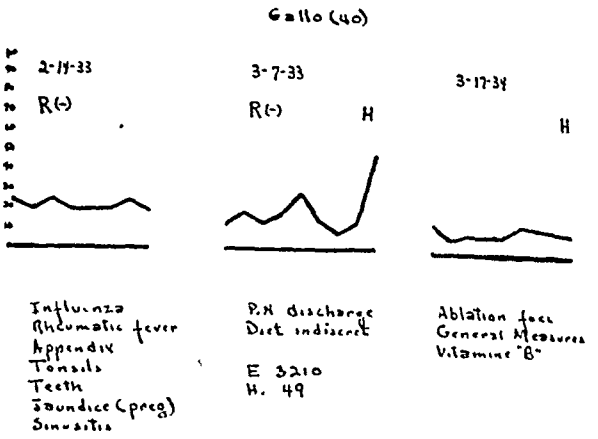

Fig. 16, Case 4. Hypochromic, microcytic anemia with gastritis and histamine refractory achylia showing the anticipated failure of secretory response to "gastritis" treatment.

complaining of abdominal pain, nausea and vomiting since June. Gastric extractions and X-ray studies suggested gastritis in a dilated retentive stomach without evidence of a circumscribed lesion. Gastric analysis showed a hypochlorhydria (Fig. 12). Possible causes for gastritis comprised scarlet fever, rheumatic fever, frequent attacks of tonsillitis, influenza and abscessed teeth. Hospitalization on an ulcer regimen improved stomach emptying and rendered her symptom-free. Symptoms recurred in December and became progressively those of pyloric obstruction, practically complete by X-ray in January 30, 1935. A gastroenterostomy was performed February 18, 1935. A stenotic pyloric ulcer was reported by the surgeon. Carcinoma of the stomach had been suspected.

Comment: It is of interest to speculate concerning the sequence of events. Those who favor a primary gastritis to account for hypochlorhydria and ulcer would undoubtedly point to the history of multiple streptococcal infections to support the contention of an antecedent pangastritis. Others might postulate that a constitutional hypo-acid diathesis accounted for the hypochlorhydria and rendered the stomach more susceptible to gastritis. A third possibility would grant a primary pyloric ulcer developing in an hypo-acid

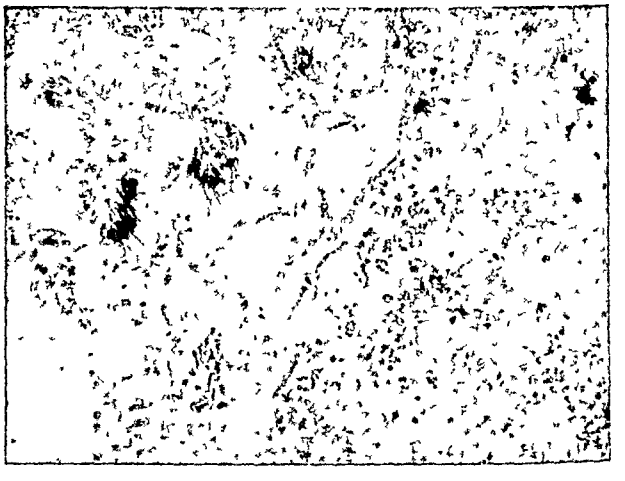

Fig. 17, Case 4. Moffitt preparation of gastric sediment aspirated through stomach tube, showing columnar epithelium in palisade arrangement in a field of mucus.

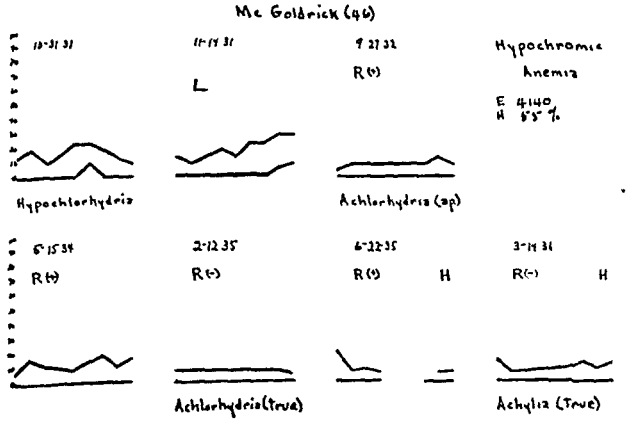

Fig. 18, Case 7. Enlarged stomach with hypochromic anemia gradually changing from an hypochlorhydria to an histamine refractory achylia in 4½ years.

stomach, the gastritis being dependent upon gastric stasis secondary to the ulcer. Somewhat against the latter argument is the rare association of juxtapyloric ulcer and hypochlorhydria. The case illustrates very well the difficulty of deciding between a primary gastritis (Faber), gastritis conditioned by a hypo-acid diathesis (Hurst), and gastritis secondary to gastric retention.

Case 8, P. B., male, 78 years old, was admitted in December, 1931, complaining of early postprandial epigastric distress for one year. Factors considered of etiological significance were frequent respiratory infections, a fondness for highly seasoned foods, diseased tonsils and arteriosclerosis. A provisional diagnosis of cancer near the pylorus was based upon his age, a short history, markedly enlarged stomach and an achlorhydria with highly cellular mucoid gastric residue. Operation was refused. The stomach decreased progressively in size and the patient improved symptomatically and in March, 1936, (4½ years later) was still carrying on. In January, 1933, he showed acid after histamine injection, which steadily diminished to a true achylia in March, 1936, (Fig. 13).

Comment: Another case of marked secretory deficiency in association with extreme enlargement of the stomach, differing from the preceding case in that gradual reduction in stomach size occurred with stomach rest. Comparable curves after histamine show progression downward to achylia from January, 1933, to March, 1936. Because of the absence of stomach symptoms until 77 years of age, it would appear that this belated achylia probably developed on the basis of an arteriosclerosis with secondary gastritis. It is conceivable that the tremendous dilatation on admission

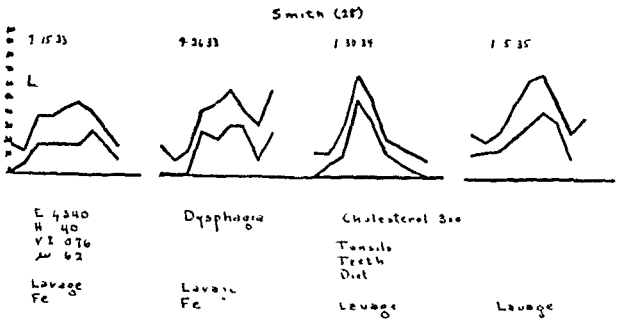

Fig. 19, Case 5. Typical hypochromic microcytic anemia changing from hypochlorhydria to normal acidity with "gastritis" treatment including lavage and tonsillectomy.

may have been due to a pyloric gastritis. Indeed both of these cases and Case 23 of the preceding group may represent examples of the stenosing type of gastritis described by Boas, Konjetzny and Faber.

True achlorhydria to true achylia. Case 31, E. M., Jewish male, 35 years of age with active pulmonary tuberculosis, slightly enlarged spleen and possibly early ileacecal tuberculosis, also had diseased tonsils and abscessed teeth. The gastric sediment suggested gastritis. The roentgen mucosal pattern in March, 1934, showed greater curvature markings which had increased in depth and irregularity in July, 1935. At this time the greater curvature showed definite speculization, a type of mucosal distortion, which we feel is most suggestive of gastritis. In August, 1933, a true achlorhydria was noted (rennet positive). Finally in March and in June, 1935, even rennet failed to appear after histamine injection—a true histamine refractory achylia (Fig. 14).

Case 27, N. S., a white male of 55 years, complained of vague distress, pyrosis and regurgitation soon after meals for three years. Oral sepsis was marked. He showed excessive quantities of fasting gastric mucoid and cellular sediment. He responded slowly to a gastritis regimen but showed a trend downward in gastric secretion from hypochlorhydria (Sept., 1929) to true achylia in November, 1933. In July, 1934, rennet reappeared after histamine (Fig. 15).

DISCUSSION, GROUP II

This group as well as the preceding one illustrates nicely the mechanism of changing gastric secretion. The trend downward is almost always gradual. In this group the secretory status diminished often in spite of clinical improvement and the recovery of gastric tonus. The first two cases (13 and 9) started from normal and receded to hyponormal in one and three years. Three cases illustrate the final stage of development of true achylia (3, 21, 27). The two older patients (56 and 78 years) slowly progressed to achylia in spite of clinical improvement. Proof is again presented to support the primary disappearance of acid with a persistence of enzyme secretion for some time afterwards. Improvement rarely occurs after the development of histamine refractory achylia. If it does, the secretion of enzyme without acid may occur, as in Case 27. The time required for the development of a true achylia is worthy of emphasis—4½ years were required from extreme hypochlorhydria to true achylia in Cases 3 and 27. The gradual depression of secretion over a period of years favors the conditioning influence of gastritis.

The age of the patient seems to be an important factor. Four of 5 patients with diminishing secretion were over 38 years of age. The other was only 35 years old but had advanced tuberculosis. After age 40 or thereabouts secretory response to treatment is less apt to occur. Whether this is due to the progression of the gastritis, decreasing blood supply, or a middle-aged hypo-acid diathesis, as suggested by the hypo-acid trend in anemic families, remains to be shown.

Lavage preceding gastric analysis has not proved as successful in immediately raising the acid level as Hurst reports—here again the age factor is significant. The degree of response both to histamine and lavage seems to diminish with age. It is noteworthy in the entire group of cases that acid response to histamine in the apparent achlorhydrias may be delayed—often until the second hour. This is mentioned because in

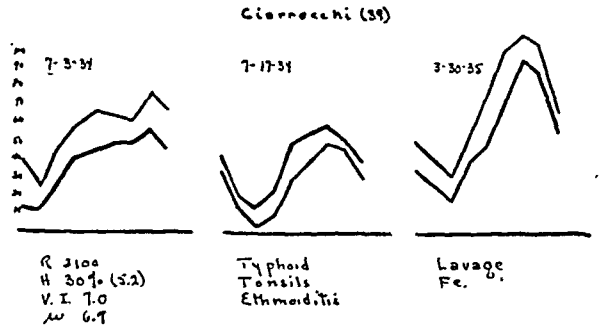

Fig. 20, Case 8. Hypochromic, microcytic anemia changing from normal to extreme hyperchlorhydria following "gastritis" management with lavage.

normal stomachs the maximum increase occurs from 15 to 30 minutes after injection. Obviously a diagnosis of histamine, refractory achylia cannot be made in cases of gastritis unless the test is continued for the full two-hour period.

Several of these cases emphasize the necessity for paying more attention to gastric retention as a possible cause for the gastritis—a factor which may account for the high incidence of gastritis in association with ulcer. Cases 13 and 9 tend to support Hurst's contention that antral gastritis is not necessarily associated with hyperacidity.

GROUP III—HYPOCHROMIC, MICROCYTIC ANEMIA

In 1909, Faber described "simple microcytic anacid" anemia and in 1913 he mentioned a typical case of this disease, which showed a characteristic follicular gastritis at necropsy. He has recently expressed the opinion that the gastritis causing the anacidity may in some way account for this type of anemia which usually responds to iron. Achlorhydria seems to be accepted as a necessary concomitant in the diagnosis of this type of anemia in many quarters. A group of cases are briefly reviewed in order to illustrate the behavior of the gastric acidity.

Case 4, M. G., a white Italian multipera, 40 years of age, complained of early postprandial epigastric distress and weakness. Factors held responsible for the gastritis were influenza, overindulgence in coarse, highly seasoned foods and coffee, frequent attacks of tonsillitis, multiple dental foci, chronic pansinusitis, nasal polyps, chronic postnasal discharge, and jaundice with a recent pregnancy. Repeated gastric lavage exhibited gastritic sediment. Tissue sections prepared from the sediment showed excessive desquamation of surface epithelium and deeper glandular elements (Fig. 17). X-ray of the stomach was essentially negative. In February, 1933, the erythrocytes were 3,210,000 and the hemoglobin 49 per cent. Frequent gastric analysis showed a true achylia gastrica which persisted in spite of therapy directed toward a possible gastritis (see Fig. 16).

Case 7, M. Mc., a white female, appeared in October, 1931, at the age of 46, complaining of alternating diarrhea and constipation, anorexia, morning nausea and retching. No etiologic factors for gastritis were elicited except for marked dental sepsis for which treatment was refused. X-ray showed a markedly dilated stomach with greater curvature serrations and irregularity. The gastric sediment was suggestive of gastritis. In June, 1934, the erythrocytes were 4,140,000 and the hemoglobin 55 per cent. X-ray at this time showed marked reduction in stomach size.

Comment: The case demonstrates a gradual reduction in gastric secretion from a marked hypochlorhydria in 1931 to a histamine refractory achlorhydria in June, 1935, and finally a true achylia in March, 1936, (Fig. 18).

Case 5, G. S., a colored female, 28 years of age, free from gastro-intestinal complaints, was first seen in July, 1933. She gave a history of excessive indulgence in hot and highly seasoned foods, and had infected tonsils and dental caries. The blood count showed 4,340,000 erythrocytes, 40 per cent (7.0 gm.) hemoglobin, 5,300 leukocytes, a volume index of 0.76 and an average red-cell diameter of 6.2 microns. The blood cholesterol was 300 milligrams and the basal metabolic rate minus 3. The gastric sediment was suggestive of gastritis. The X-ray was essentially negative. The special tissue preparation of the gastric sediment was of no significance. Recurring bouts of dysphagia developed soon after treatment was started.

Comment: Startling with a marked hypochlorhydria the secretory trend was definitely upward. This may have been due to stomach rest, therapeutic gastric *lavage or removal of diseased tonsils (Feb., 1935)*. The anemia responded satisfactorily to iron (Fig. 19).

Case 8, M. C., an Italian female, 39 years of age, was first studied in July, 1934, giving a history of typhoid fever, frequent sore throats, chronic ethmoiditis, long-standing constipation, and having grossly diseased tonsils. The blood-count showed 3,100,000 red-cells, 30 per cent or 5.2 grams of hemoglobin, reticulocytes 0.5, volume index 0.7, average size of red-cells 6.7 microns. Lavage caused the recovery of excessive gastritic sediment. The stomach films were negative except for a serration of the proximal half of the greater curvature. A normal acidity was present in July, 1934. The patient was given therapeutic lavage at frequent intervals, put on a smooth diet, the bowels were regulated and iron therapy started. In March, 1935, the acidity curve was that of a grade 3 hyperacidity (Fig. 20).

Comment: The case illustrates the occurrence of a typical hypochromic microcytic anemia with a normal gastric acidity changing to a high-grade hyperacidity after the institution of therapy directed toward a possible gastritis and treatment of the anemia with iron.

Case F., M. G., a colored female, age 31 years, was first seen in January, 1933. She was free from gastro-intestinal complaints and was being followed in the medical clinic for symptoms attributable to anemia. The red-cells were 4,830,000, hemoglobin 55 per cent, or 9.5 grams, leukocytes 4,000, reticulocytes 0.3 per cent, volume index 0.75 per cent, Wassermann positive. The stomach acidity was normal and the fasting and lavage sediment suggested gastritis. The Moffitt preparation of the sediment showed neutrophils, degenerated cells from the gastric mucosa and nuclear remnants. The anemia responded to iron. In April, 1935, she was placed on therapeutic lavage and the tonsils were removed. In February, 1936, re-ray indicated a slight tendency toward irregularity of the greater curva-

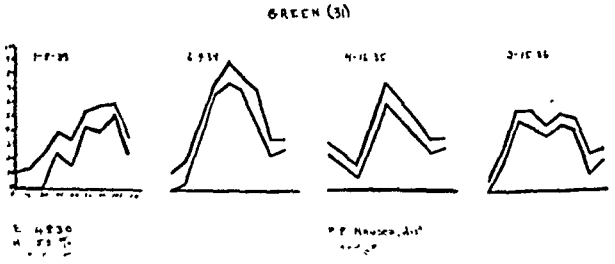

Fig. 21, Case "F." Hypochromic microcytic anemia with normal acidity and hyperacidity.

ture of the stomach, suggestive of gastritis. The gastric acidity curve mounted in June, 1934, then returned to normal (Fig. 21).

DISCUSSION, GROUP III

Five female patients with hypochromic microcytic anemia are presented in order to emphasize the frequent occurrence of all varieties of gastric secretory behavior in this type of anemia. The three younger patients had normal acidity. Three other patients have been followed with typical hypochromic microcytic anemia, originally having a normal acidity, who subsequently became achlorhydric. They were not included in this group because special examinations for gastritis were not performed. Cases 5 and 8 show that actual improvement in the acidity level may follow treatment in the younger age group. Case 5 with an extreme microcytosis started with a definite subnormal acidity and later had normal secretion. The status of this case is further fortified by the development of dysphagia, simulating a Plummer-Vinson syndrome without achlorhydria. The two older patients, Cases 4 and 7, showed a low secretory level, one gradually developing a true achlorhydria after 4 years and the other showing a true achylia from the start. The secretory behavior in these cases does not support the pathogenetic importance of a primary achlorhydria in hypochromic, microcytic anemia.

The cases were segregated from material considered clinically to have gastritis, although the proof of the gastritis was not always irrefutable. All had an excessive amount of gastric sediment in the fasting residuum and after astringent lavage. Roentgen evidence was not striking but was suggested in Cases 8, 7 and F. Histologic study of sections prepared from the gastric sediment suggested excessive desquamation and degeneration of gastric mucosa in Cases 4 and F. The elevation in gastric acidity in Cases 5 and 8 would be considered by Hurst and Faber as evidence strongly suggestive of an underlying gastritis. The very gradual depression in acidity over a four-year period in Case 7 corresponds to the manner of development of achlorhydria in gastritis described by Faber.

The group analysis suggests a common factor of gastritis and supports, in some measure, the contention of Faber that the anemia results from a primary gastro-duodenitis interfering with the elaboration of a specific antianemic factor. This mechanism would explain the frequent absence of achlorhydria until the gastritis has become general or until the gastritis has decreased the utilization of vitamine B, sufficiently to interfere with normal-acid secretion. The "gastritis" theory does not sufficiently explain the sex peculiarity of the anemia and our cases strongly suggest a concomitant thyroid-ovarian dysfunction, which must be woven into the pattern of hypochromic, microcytic anemia before it is complete. Nevertheless, we feel that complete therapy must include attention to the gastritis which is probably almost always present. There is nothing in the study of these cases which refutes the existence of an underlying familial or constitutional diathesis accounting for an increased susceptibility to either gastritis or anemia or both. Indeed, this may constitute the connection with the endocrine system and account for the difference in secretory behavior which seems somewhat related to the age of the patients.

SUMMARY

The gastric secretory behavior of a group of cases with suggestive clinical evidence of gastritis has been studied for periods varying from 3 months to 6 years. Gastritis in association with ulcer and cancer and with primary hyperacidity are not included.

For purpose of analysis these cases were divided into 3 groups: (1) those with absent or reduced acidity, showing improvement in the secretory status following treatment; (2) those with low sustained or diminished levels of gastric secretion and (3) a group having in common a hypochromic microcytic anemia.

Therapeutic measures of possible significance in improving the secretory status are discussed and illustrated. Marked improvement in the level of secretion may occur in any patient who does not show a true histamine refractory achylia, but the chances of a sustained elevation in secretory status diminishes with the degree of secretory suppression originally encountered. Clinical improvement usually parallels increased secretion in the hypo-acid group but may occur in many cases in which no elevation in the secretion curve takes place.

The most important factor influencing the secretory response to therapy is that of age. States of reduced secretion, except true achylia, occurring in patients under 35 years of age frequently show improvement. After the age of 40, such improvement is less commonly encountered. The amplitude of the immediate secretory excursion after histamine injection or gastric lavage in hyposecretion states is likewise diminished after age 40. If a hypochlorhydric or achlorhydric diathesis exists, it must remain latent in most instances until middle life. The relative significance of gastritis and of a so-called hypo-acid diathesis in achlorhydria is discussed.

The trend upward in acidity in hypochlorhydria or achlorhydria may occur very rapidly, but the trend downward is usually very slow and methodical. Evidence is presented to indicate that true achylia may not occur until many years after the acidity has started to fall. The secretion of gastric enzymes practically always persists for a time after acid secretion has ceased.

The response to histamine injection may be delayed much beyond 30 minutes in cases of chronic gastritis with apparent achlorhydria.

Three cases are included with extreme gastrectasia and hypochlorhydria, which may have depended upon a stenosing type of gastritis as described by Faber, Konjetzny and Boas.

Evidence is presented which suggests that hypochromic, microcytic anemia which responds to iron therapy may be conditioned primarily by gastritis. The anemia is often found in the absence of achlorhydria. The significance of gastritis in this type of anemia is discussed.

DISCUSSION

DR. BURRIL B. CROHN (New York City): Dr. Bockus' modest last statement really constitutes my discussion. I feel like the witness who is before the Congressional Committee and to inquiries says that either he forgets or he doesn't know. When it comes to talking about gastritis I feel the same way. I do not know what gastritis is. I do not think that anybody can definitely say

what constitutes gastritis either pathologically, clinically, from the standpoint of secretory changes, and certainly not from the clinical behavior of the patient. Certainly the clinical diagnosis of the gastritis is just about the most dangerous ground to step on that I can possibly imagine.

I am glad to see Dr. Bockus take up the study of gastritis. I believe that Dr. Bockus described in previous years the secretory changes of an anacid nature taking place with advancing years. The acid curve is at its maximum about the age of 20; the incidence of anacidity gradually progresses and reaches a maximum at the age of 55. I wonder whether Dr. Bockus is implying now that that gradual diminution of acidity is based upon actual pathological changes in the mucosa of the stomach wall, in the nature of gastritis.

I wonder if any two or three pathologists sitting down to the microscope with the same slides would agree to what constitutes gastritis, whether the small increase of round cells, plasma cells and leucocytes constitutes a disease; and, if the increase of cells is a disease, whether that disease is capable of diagnosis as gastritis?

Missing from Dr. Bockus' paper are the gastroscopic pictures. If we are to depend at all on the diagnosis of gastritis one would want gastroscopic confirmation and would want more histological findings to parallel these changes.

In the old days we recognized gross variations in gastric secretion. We spoke a great deal at length about the variations in gastric secretory curves in the same individuals under varying conditions and we recognized that there was no such thing, even in the same individual, as an identical curve under all conditions.

I just wonder if Dr. Bockus in showing these various curves during states of debility, for instance, in contrast to states of increased health, whether these variations and fluctuations in acidity aren't greatly dependent upon functional and secretory changes rather than on actual organic changes in the mucous membrane?

DR. H. L. BOCKUS (closing the discussion): I should like to take this opportunity to apologize to Dr. Crohn for not having given him the paper previous to the meeting. Unfortunately the illustrations were not completed in time.

There are several points mentioned by Dr. Crohn that I shall try to elaborate on a little. First of all the diminution in the levels of stomach acid. That is open to a number of interpretations, as Dr. Crohn well knows. If you talk to Dr. Knud Faber, he will tell you that this is definitely indicative of and dependent upon gastritis. Dr. Hurst on the other hand feels that the gradual diminution in acid results from gastritis conditioned by an hypoacid diathesis. We were able to confirm Dr. Hurst's contention that he has never seen a hyperacidity in diffuse gastritis gradually give way to a true achylia. We have looked carefully for a case of that type and, to our surprise, so far we have not found one.

As far as gastroscopy is concerned, most of these patients were examined through the gastroscope. I do not feel so confident as Dr. Crohn apparently does that one can make invariably a definite diagnosis of gastritis by gastroscopy. We have looked at over 150 stomachs in that way, and I feel that there is a great need for further study and classification before one's experience justifies a diagnosis of gastritis based entirely upon the gastroscope.

We have had a conservative roentgenologist collaborating with us and we are not prepared at this time to say anything about the roentgenologic findings. In some instances the roentgen findings have been characteristic, but one should not expect to find X-ray evidences of gastritis in every case, and naturally the mucosal pattern differs greatly in gastritis.

I reiterate my previous statement that we have no absolute diagnostic criteria for the diagnosis of this type of gastritis, either through the gastroscope or the X-ray or the examination of the gastric sediment. All three methods should be utilized. We should like to see enough interest stimulated so that all of these methods will be used in various places, hoping that at some later date an established criterion for the diagnosis of gastritis of various types will emerge.

Dr. Crohn mentioned the slight changes in our acid curves. The changes were not slight. They were great, particularly in the younger patients whose acid levels mounted. The upward trend in some instances was phenomenal. The mechanism of changes in gastric acidity of the type mentioned is not always clear. It may depend upon removal of a mechanical impediment to the flow of juice, such as mucus in the gastric tubules, or rapid diminution in the size of swollen cells, or it may be due to improvement in a deficiency state which has conditioned the hypoacidity or anacidity, or upon other factors little understood.

Intracutaneous Responses, Comparable to Positive Frei Reactions, with Colonic Exudate from Chronic Ulcerative Colitis Cases with Positive Frei Tests*

By

MOSES PAULSON, M.D.†

With the Technical Assistance of

Betty Kravetz

BALTIMORE, MARYLAND

THERE was reason to believe that among cases classed as idiopathic ulcerative colitis, with and without stricture, some might be due to a virus or viruses, probably to the virus of lymphogranuloma inguinale. If proved, a virus as a cause of intestinal disease would come into being, and the idiopathic ulcerative colitis group would be further narrowed. In this connection, it was recognized that a positive Frei test indicating the past or present presence of lymphogranuloma inguinale in a patient with an otherwise unexplained ulcerative colitis did not of itself prove that the causative L.i. virus was etiologically related to the colitis. It was conceivable, in some instances at least, that the colitis might not bear any relation to an antecedant, simple, uncomplicated and healed infection, as reminded by the positive Frei intradermal reaction. Also, it was recognized that the mere presence of a virus was neither proof of the presence of disease nor responsible for the disease with which it appeared to be associated. However, the first step in attempting to demonstrate colitides of possible virus origin, rested in the isolation or indication of the presence of such an agent directly from the suspected colonic involvement. It is with these attempts that this communication is concerned.

It was hypothesized that if antigens could be prepared from bowel material of those with ulcerative colitis having a positive Frei test, which would give comparable reactions with the Frei antigen, and if the test antigen responses could not be ascribed to foreign protein, to a known bacterium or toxin, that such results consistently secured might indicate the probable presence of a virus or viruses in such intestinal exudate.

PROCEDURES

I. Sources:

(A) Cases presenting a positive Frei test with an otherwise unexplained ulcerative colitis with and without stricture but without elephantiasis or vegetations.

(B) Cases presenting a negative Frei test with an unexplained ulcerative colitis.

(C) Cases presenting a negative Frei test without colitis.

II. Methods:

Since it was desirable here to work with bowel material free from bacteria, and since the virus of L.i. is considered by some to be filterable, filtration experiments were done as follows:

(A) Preparation of Antigen. A few hours following saline enemas, patients were rectosigmoidoscoped and about 1 to 5 c.c. of grossly fecal-free material usually of a muco-purulent nature with or without gross blood, were aspirated into a large tube containing glass beads and 5 c.c. infusion bouillon. Sterile technique was employed throughout. This material was then well shaken and bouillon dilutions of 1:5 or 1:10 were made. This was filtered through sterile non-absorbent cotton to remove larger particles which interfere with filtration, and then passed through Seitz and Berkfeld V or N filters.* The bowel filtrate was then heated at 60° C. for two hours and on the following day for one hour.

Aerobic and anaerobic sterility tests were done immediately after passage through the filter, after heating, and after the addition of 0.25% phenol for preservative purposes.

(B) These antigens were then inoculated intradermally in the same amount as is the Frei antigen: 0.1 c.c. The results were read at 48 hours and 9 days; in many instances readings were made at later dates. Intradermal inoculations usually with more than one known active Frei antigen were done simultaneously for comparative purposes.

RESULTS

1. *Two Seitz-filtered bowel antigens* from two ulcerative colitis cases with positive Frei tests, one with and one without stricture, were tested on seven cases exhibiting positive Frei reactions. All were unquestionably negative. In no instance did the reaction attain a size of more than 2 mm., and that only once.

2. *Nine Berkfeld-filtered bowel antigens* from five ulcerative colitis cases with positive intradermal Frei reactions and from four such cases with negative Frei responses, were tested upon six cases exhibiting positive and five negative Frei tests. One of the positive Frei cases gave intradermal indurations in excess of 5 mm., with two antigens from ulcerative colitis cases evidencing positive Frei tests, at 48 hours. One week later—nine days after inoculation—these reactions had disappeared. This was not regarded as of significance in view of the fact that all of the remaining cases

were definitely negative and the reaction did not persist for at least 9 days.

In view of the apparent inability to demonstrate the presence of any reaction-producing substance in filtered bowel exudate by this method, attempts were then made to prepare antigens of unfiltered material. It was collected in the manner already described and diluted 1:5 with saline. This was then heated in sterile vials at 60° C. for two hours, and for one hour on the following day. Aerobic and anaerobic sterility tests were made after heating and again after the addition of 0.25% phenol for preservative purposes. Dilutions were prepared as further indicated in the Charts. 0.1 c.c. was inoculated intradermally and the readings were obtained usually at 48 hours, at 9 days, and in many instances later. Twenty-four attempts to secure material from nine cases of ulcerative colitis evidencing positive Frei tests resulted in the obtaining of three antigens. Two of these ("J" and "McK" antigens) were free of viable bacteria. In one ("O.L.") an alpha-zoned (green producing) enterococcus persisted. This antigen was used despite the presence of the organism, for reasons to be discussed later. In the remainder, more than one type of organism survived. This also occurred in each of eight attempts from five ulcerative colitis cases with negative Frei reactions. Such material was discarded.

Intradermal inoculations with known active Frei antigens were done simultaneously for comparative purposes. Intradermal reactions for chancroids in the human sources of the three test antigens employed were negative. Intestinal tuberculosis was eliminated.

RESULTS

The three antigens were tested on six ulcerative colitis cases with positive Frei reactions. The controls consisted of thirteen cases presenting negative Frei responses; three were diagnosed as ulcerative colitis, two as chronic indeterminate diarrhea, and eight as functional dyspepsia.

Criteria used in determinations: The preparation of the antigens from unfiltered bowel material, the

method and amount of inoculation—as already noted—and the interpretation of the results were identical with that employed in the Frei technique. These criteria are those expressed by Wassen (1) with respect to the Frei reactions:

"The reaction is not read off until after 48 hours and a reddened and infiltrated dome-shaped papule is considered positive only if its diameter is at least 5 mm. . . . A positive reaction remains for a rather long time, as much as 8 to 12 days, as opposed to a non-specific reaction which is frequently very acute but also very transient."

It is to be added that the papule may go on to necrosis, that induration may on occasion be found to be more prominent that actual papule formation. The erythema extending beyond or that which is not associated with the papule or induration is not considered in the measurements.

SUMMARY OF TABULATED DATA

1. On the basis of the criteria just outlined, a perusal of Charts I, II and III indicates that all six cases of ulcerative colitis with positive Frei tests gave positive responses at 9 days after inoculation with one or more bowel exudate antigens. Of these, three cases (No. 2, No. 3 and No. 5) were positive with all three antigens, case No. 4 tested with two antigens was positive with both, case No. 1 was positive with two of three antigens, and case No. 6 with one of two antigens. Cases No. 2, No. 4 and No. 6, which reappeared for observation at 14 days, were still positive: case No. 2 was positive with two of three antigens, case No. 4 with two of two; and case No. 6 with one of two.

2. Of the thirteen negative Frei control cases submitted to bowel exudate antigens (Charts IV, V, VI), no definite positive intradermal reactions were obtained in any by the criteria outlined. Eight (cases No. 4, No. 5, No. 6, No. 7, No. 9, No. 11, No. 12 and No. 13) were negative with all three antigens; three (cases No. 1, No. 2 and No. 3) tested with two antigens were negative with both. Of the two remaining cases (No. 8 and No. 10) inoculated with three antigens, each presented one doubtful reaction: case No. 8 with the "O.L." antigen was positive at five days but negative at 12 days; case No. 10 with "McK" 1:15 antigen was not positive at 9 days but was at 16 days; they were negative with the other two antigens used.

3. Of the six ulcerative colitis cases presenting positive Frei responses, all revealed persisting reactions in excess of 5 mm. to the known active Frei antigens used at the end of 9 days. In the three cases observed on the 14th day, they were still positive.

DISCUSSION AND INTERPRETATIONS

The inability to demonstrate a substance indicative of a virus or some other significant agent in the filtered bowel exudate of those in whom such presence is suspected with this method, is in line with two unsuccessful attempts to obtain positive intracutaneous responses from Berkfeld (V and N) filtered bubo pus known to give positive Frei reactions when unfiltered. From a few such experiments with the virus of lymphogranuloma inguinale, Wassen (2) considers it is filterable. It has been passed through Chamberlain L1, L2, L3, and Berkfeld filters. However, this appears to have occurred irregularly, inconstantly. The Chamberlain type of filters referred to above are quite coarse allowing bacteria to pass, and hence were inapplicable to this work. The possible reasons for the negative results here with Berkfeld and Seitz filters were the slight concentration and virulence of the possible virus or its absorption by the filters.

It is believed that the constant and striking intracutaneous responses in those with ulcerative colitis and positive Frei tests and the negative intradermal reactions in those with negative Frei tests (controls), with antigens prepared, in consequence of filtration obstacles, from unfiltered bowel exudates of those with ulcerative colitis and positive Frei tests, are indicative of the presence of a specific substance or substances, probably of a virus nature. It seems likely that of the possible viruses, that of lymphogranuloma inguinale is present.

These skin responses to antigens of unfiltered bowel exudate are not purely of a bacterial nature. The cases from which the materials were secured for the preparation of these antigens were found negative for the Ducrey bacillus infection by means of the specific intradermal test for chancroid. The gonococcus, another possible cause, and syphilis, which rarely is re-

sponsible for conditions not unlike these studied here, give no specific reactions by a method such as this. Tubercle bacilli would not seem to be etiologic agents in these cases since such distal colonic involvement is usually a terminal stage of pulmonary tuberculosis and none here was tuberculous. Besides, the tuberculin test when positive persists usually for no more than 3 to 4 days. In this connection, it should be added that one of the antigens, "O.L.", despite the presence of a living alpha-zoned (green producing) gram positive enterococcus, and which was used only because of difficulties encountered in preparing an adequate number of unfiltered bowel antigens, gave the typically positive and negative responses in the positive and negative cases paralleling the reactions from both the test antigens containing no viable bacteria and the known active Frei antigens.

The responses with unfiltered bowel exudate antigens do not seem to be due solely to foreign protein or to toxins. Such reactions are relatively acute and transient. In the ulcerative colitis cases with positive Frei tests, the intracutaneous responses of 5 mm. or more persisted with undiminished size for at least 9 days and in nearly all cases for two weeks. In the negative Frei test (control) cases, the reactions were always under 5 mm. and did not manifest the same tendency to persist.

Thus, these skin responses cannot be considered either as a specific reaction to a known bacterium, toxin or as a result of foreign protein. These cutaneous allergic responses paralleling those produced by active Frei antigens are believed to be indicative of the presence of an inciting agent, unlike any of the above, possibly that of a virus. The recent research of Levaditi and his co-workers (3) appearing in April, 1935, while this work was in progress, is in line with this viewpoint.

The fact that the skin reactions with unfiltered bowel exudate antigens parallel known active Frei antigens does not of itself prove that the reaction is due to the inactivated virus of lymphogranuloma inguinale. It is possible that this may represent the presence of more than one virus. It is also possible that a distinctly different virus may give a reaction indistinguishable from that of Frei. Frei and Koppel (4) attempted to show the relationship between inguinal adenitis due to the virus of L.i. and genital and ano-rectal lesions by histopathologic methods. Frei later indicated (5) that this proof was incomplete. However, the experimental work of Levaditi and his co-workers referred to above indicates the unity of the etiology of lymphogranuloma inguinale and some cases of ulcerative colitis with positive Frei tests. Levaditi, in confirmation of the earlier hypothesis of Ravaut and his co-workers (6), reproduced the disease of lymphogranuloma inguinale in two with general paresis. The original source of the infective material was a biopsy specimen of an ano-rectal lesion from one with a positive Frei test. The patients prior to the inoculation presented negative intracutaneous reactions with Frei antigens and the antigen from the test material. After the establishment of the disease, the responses to these antigens were positive.

Attention is directed to the fact that the material employed by us and believed to contain the inciting agent, probably a virus, was a muco-purulent, some-

what sanguinous colonic discharge and not biopsy tissue. Two of the three sources of the three antigens used presented ulcerative colitis complicated only by rectal stricture; the third, "O.L." presented no pathology other than that of an uncomplicated ulcerative colitis. This indicates that this substance may be in the lumen of the intestine without the necessary presence of elephantiasis, stricture or vegetations. Thus, ulcerative colitis may not only be brought about by dysentery and tubercle bacilli and E. histolytica, but also possibly by the virus of L.i., and probably by other viruses. The only reference encountered to work of a similar nature is that by Nicolas, Favre, Lebeuf and Charpy (7), who secured one antigen from the pus exuding from a fistula of one with ano-rectal elephantiasis with a positive Frei test. In three cases with positive Frei tests, this antigen gave positive responses. No control work of any nature is reported.

CONTROL STUDIES

One case (Chart VI, No. 6) showed a positive response at 48 hours, but was negative at 9 days; this was regarded as a foreign protein reaction because of its lack of persistence. Case No. 8 showed a positive skin reaction with unfiltered bowel antigen at five days, but was negative at twelve days. This was considered doubtful because of its lack of persistence. If one chooses to consider this reaction as positive, it is the only deviation in the thirteen controls tested. The intradermal response of "McK" 1:15 antigen in case No. 10 was negative at 48 hours and 9 days, but positive in 16. This unusually belated response cannot be satisfactorily explained. Even though Frei tests giving no significant reactions at 9 days are regarded as negative, this response has been classed as doubtful. In this connection it should be noted that the above cases No. 8 and No. 10 were found negative with the single active Frei antigen with which they were tested. It was impossible to secure their return for further intradermal studies with other known active Frei antigens. Incidentally, all other cases except case No. 1 in the positive group, were tested with more than one known active Frei antigen.

Due to insufficient unfiltered bowel exudate antigens from those with ulcerative colitis with positive Frei tests no control studies could be undertaken among those never having had colitis but who presented positive Frei reactions. Control studies with unfiltered bowel exudate antigens from ulcerative colitis cases and from other sources both with negative Frei tests have not been done. As has been noted elsewhere, it has been found impossible to date to procure additional antigens free from viable bacteria. Such attempts, however, are being continued. The securing of adequate antigens from only a few ulcerative colitis cases with positive Frei tests would seem to have been a fortuitous circumstance, since it is impossible to predict when, with the identical technique, another antigen will become available. In most instances the heat used to inactivate the possible virus or inciting substance prior to intradermal inoculation is insufficient to destroy all of the intestinal bacteria in such material. We are not oblivious to these shortcomings and are still attempting to overcome them.

The significance of this work rests in the suggested presence of a virus which may bear a likely relationship to the etiology of one type of ulcerative colitis. These findings bring into being the further likelihood of the presence of other viruses in the alimentary apparatus. These may clarify the present uncertain etiologic knowledge of many phases of digestive disease.

SUMMARY

There is reason to believe that some cases classed as idiopathic or non-specific ulcerative colitis, with or without stricture, may be due to a virus or viruses. Cases of ulcerative colitis of undemonstrable etiology were selected in whom the possible presence of a virus in the colon might be etiologically related to the colitis as suggested by their having positive Frei reactions. Attempts were made to prepare antigens of bowel exudate for intracutaneous tests in accordance with the Frei technique. Filtering this material through Berkfeld V and N and Seitz filters resulted in the obtaining of antigens giving negative responses. Unfiltered bowel exudate antigens were prepared from three cases of ulcerative colitis, two with stricture and one without, presenting positive Frei tests and negative intracutaneous responses to the Ducrey bacillus antigen.

There were obtained striking intracutaneous responses of 5 mm. or more in diameter, persisting for at least 9 days in six ulcerative colitis cases with positive Frei tests, and negative responses in at least 12 of 13 control cases with and without colitis and with negative Frei tests.

The significance of these cutaneous allergic responses, paralleling positive reactions with known active Frei antigens, suggests the presence of an inciting agent unlike a toxin, a specific bacterium or foreign protein, possibly a virus or viruses, within the intestine of man. This may bear a relationship to the etiology of one type of ulcerative colitis, and brings into being the likelihood of the presence of other viruses in the digestive apparatus. These may clarify the present uncertain etiologic knowledge of many phases of digestive disease.

DISCUSSION

DR. H. NECHELES (Chicago, Illinois): Dr. Paulson demonstrated that persons with a positive Frei reaction

(F.R.) and colitis have a substance in their colons which produces a positive Frei reaction in this same group. This brings up several questions: Can it not be that all of these six patients have had lymphogranuloma inguinale (L.I.)? In the literature cases have been described with slight L.I. and with no suppuration. Many more such unrecognized cases with positive F.R. may occur and in some colitis may develop accidentally.

A positive F.R. signifies a certain immunity against the virus. It is thinkable that after the healing of the L.I., the virus may persist in the colon of these persons, especially women (were the patients male or female? white or colored?). Therefore, it seems to me the question has to be answered whether persons with a positive F.R., but not suffering with colitis, harbor this virus in their colons.

The virus of L.I. is not known. The proof that it may cause colitis so far is circumstantial. Therefore the following questions must be asked.

a. Can one produce colitis with virus of L.I.?

b. Can material from the colons of persons with colitis and positive F.R. cause L.I. in man and encephalitis in animals.

Clinically and pathologically both diseases are very different. Colitis is a disease of the mucosa. L.I. is a disease of the lymphglands.

French authors, especially, have stressed the effectiveness of antimony therapy in L.I. If this is true, good results ought to be obtained also in colitis with positive F.R.

One must not forget that besides the theory of bacterial or virus causation of colitis there is a yet unanswered physiological side to it. I am thinking of the importance of the colon as excretory organ and as organ sensitive to changes in intermediary metabolism. Changes of permeability through abnormal excretions, changed pH, pathological intermediary metabolism, may produce inflammation and ulceration of the colon, and the host of organisms present in the colon may then produce a secondary infection.

Colitis patients frequently represent a certain nervous type of person, and hypermotility of their colons may indicate an increased number of nervous impulses to it. I have found the colon to respond more to acetylcholine (a.c.) than the upper G.I. tract. Stimulation of parasympathetic nerves produces a.c.; a.c. effects strong contractions of the colon and possibly, as we have been able to show in the case of the stomach, vasoconstriction. This may be followed by focal necroses, autolysis or digestion, and secondary infection by the host of bacteria always present in the colon.

DR. MOSES PAULSON (closing the discussion): I do not mean to infer that a virus has been actually isolated. I mean only to state that a substance or substances has been found in the colonic exudate from some with ulcerative colitis and positive Frei tests, which when prepared after the manner of the Frei antigen, give intracutaneous reactions paralleling the positive Frei responses. The colonic exudate antigen responses do not seem to be due to the antigenic qualities of specific bacteria, a toxin or to foreign protein. It is my supposition that they represent an immunological reaction to substances of a virus character. This allergic response may be in consequence either of the virus of lymphogranuloma inguinale or of other viruses or substances giving a like response. In this connection, the mere presence of a virus would not in itself mean that it is the cause of the disease with which it appears associated. My purpose here was to demonstrate a product in the human intestine unlike any with which we have heretofore worked. Eventually such may throw new light upon some of the digestive manifestations of obscure etiology.

In answer to the question as to sex and color—five of the six were women, and five of the six were colored.

The Diagnostic Significance of Anti-Dysentery Bacteriophage*†

By

THOMAS T. MACKIE, M.D.
NEW YORK, NEW YORK

THE possibility that certain types of seemingly nonspecific chronic enteritis and colitis may be in fact chronic bacillary dysentery has increased interest in diagnostic procedures. It has long been known that anti-dysentery bacteriophage is commonly encountered in the stools of patients convalescent from the acute form of the disease. Recently the significance of this lytic principle in chronic infections has been investigated, and the term "diagnostic bacteriophage" has been introduced. Felsen (1) has obtained the "diagnostic bacteriophage" from certain cases of chronic ulcerative colitis. Similarly Winkelstein and Herschberger (2) found a phage present in 36% of 41 cases of ulcerative colitis, and absent in 45 miscellaneous controls. This finding they state "seems to have some significance" and they conclude "The finding of a bacteriophage active for one or more strains of bacillary dysentery organisms, is indirect but suggestive evidence that the patients have had or are suffering from bacillary dysentery."

The specificity of action of unadapted bacteriophage obtained from stool filtrates is open to question. According to d'Herelle (3) each bacteriophage that may be isolated in nature possesses a mosaic of lytic activities and each of these may vary in degree. He has stressed the seemingly fortuitous character of the range of bacterial species lysed by any given phage. One race of bacteriophage may be active only against certain strains of E. coli, while a second may exhibit in addition lytic activity against E. typhosus or S. dysenteriae or both. Burnet (4) likewise states that very few phages have their activity limited to a single bacterial species, and many are capable of attacking a wide range of intestinal bacteria. Others (5) state that a lytic principle active against S. dysenteriae

frequently can be isolated from individuals not suffering from dysentery.

AUTHOR'S STUDY

We began a study of the diagnostic significance of anti-dysentery bacteriophage several years ago in the course of an investigation into a possible relationship between chronic bacillary dysentery and non-specific ulcerative colitis. We (6) encountered a lytic principle in 34% of a group of cases of chronic ulcerative colitis and in 10% of ninety control cases. Our experience was summarized as follows: "It is impossible to evaluate the significance of bacteriophage. While it is present in a considerably larger number of cases of ulcerative colitis, it occurs frequently in the absence of demonstrable infection by B. dysenteriae. Similarly it was found in a small proportion of the control group apparently free from infection." Further experience has confirmed our original statement and suggests the necessity for strict qualification of the term "diagnostic bacteriophage." In view of this it has seemed desirable to present our observations in detail.

TABLE I—GROUP I

Incidence of bacteriophage in cases with positive culture or agglutinins

Total Cases: 84	Bacteriophage Present	Bacteriophage Absent
Positive culture	8	15
Agglutinin titre 1/160 or above, negative culture	8	24
Agglutinin titre below 1/160, negative culture	6	23
Totals	22	62
Incidence of Bacteriophage in entire group		26.2%
Incidence of Bacteriophage in cases with good evidence of S. Dysenteriae infection		29.1%

One hundred and seventy individuals have been studied. They comprise a considerable group of cases of chronic ulcerative colitis, a small number of intestinal protozoal infections and a large number of miscellaneous conditions. For the purposes of this investigation they have been divided into two groups. The first group includes all cases presenting positive culture or demonstrable agglutinins against Shigella dysenteriae in their blood. The second group comprises those cases who afforded neither cultural nor serological evidence of infection by these organisms.

METHOD

Approximately 3 c.c. of freshly passed fecal material were emulsified in 50 c.c. of sterile meat infusion broth pH 7.3 to 7.4 and incubated over night at 37° C. Gross suspended matter was then removed by centrifuge and the supernatant fluid was filtered through a Berkfeld filter. 0.5 c.c. of the filtrate was then added to tubes containing 3 c.c. of lightly seeded 3 hour broth cultures of our laboratory strains of *S. dysenteriae Shiga* serological variants of Flexner, and Sonne-Duval. A second set of broth tubes, inoculated at the same time with the homologous strain but without subsequently added filtrate, were set up as controls. Both sets of tubes were then incubated at 37° C. and observed at intervals up to twenty-four hours for clearing of the turbidity. The stock strains of *S. dysenteriae* used were further tested for freedom from autogenous bacteriophage by the plate method.

RESULTS

Group 1 includes eighty-four patients from whom positive cultures were obtained, or whose sera contained demonstrable agglutinins for strains of S. dysenteriae, irrespective of the titre. No cases of acute bacillary dysentery are included. All the cases with intestinal symptoms were clinically chronic and in numerous instances positive cultures, and, or, positive agglutination reactions were obtained repeatedly. An anti dysentery bacteriophage was present in the feces of 22 of these, an incidence of 26.2%. If cases with negative culture and low titre agglutination reactions are excluded and the group is thus restricted to those individuals who present acceptable evidence of infection by S. dysenteriae the incidence of bacteriophage is increased to 29%. (Table I).

TABLE II—GROUP I

Cases with bacteriophage and positive culture or agglutinins

Total Cases: 22	Cases	Culture	Agglutinin Titre 1/160 or Above	Agglutinin Titre Below 1/160
Achlorhydria	1	0	0	1
Acute Salpingitis	1	1	0	0
Amebiasis	1	0	1	0
Bacterial Endocarditis	1	0	1	0
Ulcerative Colitis	18	7	6	5
Totals	22	8	8	6

Eighteen of the twenty-two cases from whom an active lytic principle was obtained were suffering from chronic ulcerative colitis. Positive cultures were obtained from seven of these patients. Six showed an agglutinin titre of 1/160 or above. The primary diagnosis in the remaining cases were respectively: achlorhydria, intestinal amebiasis, subacute bacterial endocarditis, and acute salpingitis. One of these apparently was a symptomless carrier of a Flexner strain and two of the others showed partial agglutination of a mannite fermenter at a dilution of 1/160. (Table II).

TABLE III—GROUP II CONTROLS

Incidence of bacteriophage in cases without evidence of infection by S. Dysenteriae

Total Cases: 86	Cases	Bacteriophage Present	Bacteriophage Absent
Ulcerative Colitis	25	6	19
Intestinal Protozoal Infections	8	1	7
Miscellaneous Conditions	53	4	49
Totals	86	11	75
Incidence of Bacteriophage	12.8%		

The *control group* comprises 86 cases who gave negative cultures and whose sera contained no demonstrable agglutinins for our laboratory strains of *S. dysenteriae*. Twenty-five of these were cases of ulcerative colitis, eight were intestinal protozoal infections, and fifty-three were miscellaneous conditions, clinically not suggestive of bacillary dysentery. Anti-dysentery bacteriophage was present in the feces of eleven of these patients, an incidence of 12.8%. (Table III).

TABLE IV

Incidence of bacteriophage in miscellaneous conditions without acceptable evidence of infection by S. Dysenteriae

Total Cases: 16	Bacteriophage Present	Culture	Agglutinin Titre
Achlorhydria	1	0	1/80
Acute Appendicitis	1	0	0
Arsphenamine Hepatitis	1	0	0
Foreign Body in Liver	1	0	0
Intestinal Protozoal Infection	1	0	0
Ulcerative Colitis	6	0	0
Ulcerative Colitis	5	0	Less than 1/160
Total	16 Cases		

DISCUSSION

Certain obvious sources of inaccuracy are recognized. The technique of bacteriophage determination is not standardized. Our methods, although differing in some respects, in general are comparable with those used by others who have carried out similar investigations. It is probable that the plate technique would reveal a higher incidence of lysis. Such a control was not practicable. Pure line S and R dissociants of our cultures were not used. Felsen has emphasized the necessity for repeated search for phage. In the majority of our cases this was not done. However, when repeated determinations were made on the same case, the results were often considerably at variance at different times. We recognize that the incidence of bacteriophage obtained in this study is therefore below that which would be anticipated, had we investigated our cases more completely. On the other hand this does not affect the question at issue: the validity of anti-dysentery bacteriophage determination as a diagnostic measure.

This experience therefore casts considerable doubt upon the diagnostic significance of bacteriophage in chronic intestinal infections when it is unsupported by corollary evidence in the form of positive culture or significant agglutination titre.

We have not been impressed by the incidence of specific bacteriophage in association with chronic bacillary dysentery. Only 29% of the cases with acceptable evidence of infection by S. dysenteriae exhibited a lytic principle active against these organisms. An anti dysentery bacteriophage was found accompanying positive culture in only 34.7% of our cases.

Moreover our experience leads us to question seriously the specificity of such a lytic principle. A phage active against our laboratory strains was obtained in 12.8% of the control cases. None of these could be suspected of infection by S. dysenteriae on cultural or serological grounds, and with the possible exception of the cases of chronic ulcerative colitis, none could be suspected on clinical grounds. We have found anti-dysentery bacteriophage in our control cases in association with such diverse conditions as achlorhydria, acute appendicitis, arsphenamine hepatitis, foreign body in the liver, intestinal protozoal infection, and chronic ulcerative colitis. (Table IV).

CONCLUSIONS

1. Anti-dysentery bacteriophage was found in only 29.1% of 55 cases presenting acceptable evidence of chronic infection by S. dysenteriae.

2. An anti-dysentery bacteriophage was found in 12.8% of 86 miscellaneous control cases none of whom presented evidence of infection by S. dysenteriae.

3. The clinical and bacteriologic significance of anti-dysentery bacteriophage in chronic intestinal infections is not as yet sufficiently well defined to justify the term "diagnostic bacteriophage."

DISCUSSION

DR. MORRIS L. RAKIETEN (Brooklyn, New York): I believe that Dr. Mackie has pointed out in his paper the specific objections that one who is interested in the phenomenon of bacteriophage would subject it to. I agree with Dr. Mackie that at the present time the term "diagnostic bacteriophage" is a misnomer.

If there are any phages that are particularly easy to isolate from a wide variety of sources, from fish aquaria, from drinking water, from gastro-intestinal contents of normal as well as sick individuals and from sewage, it is dysentery bacteriophage.

Dr. d'Herelle has isolated many thousands of so-called dysentery bacteriophages in the last 20 years, and I believe that he has not more than three so-called specific dysentery phages against *Shigella dysenteriae*. Most of them have typhoid, parathyhoid, coli, as well as most of the dysentery organisms.

So, when one claims to have isolated a dysentery bacteriophage, that particular claim is open to objection.

Now, it is one thing to assume as did d'Herelle, Dr. Costa Cruz, Pasricha, and Morrison, those particular investigators being interested in fields where dysentery is epidemic, especially in South America and in India, and to have shown that in cases of epidemic dysentery, that with convalescents one can demonstrate a bacteriophage; and with a demonstration of that bacteriophage a disappearance of the organism; but it is another thing to state, when one does find a so-called dysentery bacteriophage in the stool that one had to have previous infection with dysentery organisms.

Now, most of the papers that have dealt with the so-called diagnostic bacteriophage—I refer to Dr. Mackie's as well as Winkelstein's, Felsen's—are open particularly

to the objection that the method that they use for demonstrating bacteriophage is the crudest method of demonstrating bacteriophage, the so-called test-tube method. It is only when isolated bacteriophage is of the maximum potency that one gets what one may call complete clearing in the test tube.

Many bacteriophages that are moderately virulent may not appear in a test-tube method. Those particular bacteriophages will be passed over since the tubes inoculated with the filtrates containing the bacteriophage will be as cloudy as the control tube.

A better and a cheaper and a much more efficient method of demonstrating bacteriophage is by a so-called cross test in which one takes susceptible cultures and tests the filtrates against these particular cultures on agur plates.

(Slide) This slide, I believe, points that out a little better. If you will notice here are some bacteriophages which lyse this particular strain, and here are the bacteriophages that lyse that one. You will notice as compared to this particular plaque that those areas are filled with colonies, and while the bacteriophage is able to manifest itself against a particular strain according to this test it does not completely lyse it as this one and that one does, but one finds these particular so-called secondary colonies.

In a test-tube method that particular phenomenon will show up as complete turbidity and might be read by investigators as no bacteriophage at all in that particular test tube.

Now, while I say that is a much better and a cheaper method than test-tube demonstration, the best method of demonstrating bacteriophage is by the so-called plaque demonstration.

(Slide) This is a strain of bacterium coli which has been inoculated with bacteriophage in these various segments. All of these bacteriophages have been diluted out to about 10-11. Now, one finds that these bacteriophages, especially this bacteriophage here, if it is clear to you, consists of these very light areas which are plaques and which are considerably different from the plaques in this particular segment. As a matter of fact, if you were close enough you could see in this segment that we would have more than one type of plaque. Some of these are large and some of these are considerably smaller.

Yet, while that is bacteriophage, if that was done in a test tube, it would show up as completely turpid as to control.

The next objection which I want to point out is the method of isolation. The best way of demonstrating bacteriophage is to take the sewage, or stool and add to it some broth. To this particular broth you add the culture for which you want to demonstrate bacteriophage. If bacteriophages are there only in small amounts they may be absorbed by dead susceptible organisms or completely overgrown by other phages. If one adds the susceptible culture for which one wishes to demonstrate bacteriophage, it does give the bacteriophage present in that sewage a chance to manifest itself.

Until more accurate methods are utilized both for isolation and demonstration, I believe the term "diagnostic bacteriophage" should be held in abeyance, especially since we know that so-called dysentery bacteriophages are probably the least specific bacteriophages that we know anything about.

DR. ASHER WINKELSTEIN (New York City): Although I have enjoyed the speaker's paper very much, I disagree with his conclusions.

The question which Dr. Mackie brings up is whether the finding of a dysentery bacteriophage in the stool is valid evidence that the patient has or had bacillary dysentery. The best evidence for bacillary dysentery is the finding of the dysentery organism in the stool and its agglutination by specific sera. Even the presence of agglutinins in high titre in the blood is only suggestive evidence.

The findings of d'Herelle, Felsen, and myself, indicate that the dysentery bacteriophage is important diagnostically. Although we have already published our findings on this subject, I wish to show one slide illustrating our studies. (Slide) We found a dysentery bacteriophage in 15 out of 41 consecutive cases considered clinically typical non-specific ulcerative colitis. In seven of these cases the phage appeared as the patients were recovering and disappeared when they were well, thus fulfilling d'Herelle's criteria of the recovery mechanism in bacillary dysentery.

Then we studied 45 consecutive controls, including several miscellaneous diarrhaes, and they did not show any dysentery bacteriophage.

From Dr. Mackie's own statistical evidence it seems that approximately a third of his cases had the phage, and that it was almost completely absent in his controls. It does not seem fair to include the 24 cases of ulcerative colitis in his controls because it may be that those cases had bacillary dysentery without the presence of a bacteriophage. Also, its complete absence in our 45 controls does indicate that it may be suggestive evidence.

Now with reference to the other point about the polyvalency of the phage. Nearly everyone has a weak B. Coli bacteriophage in the stool. It is certainly possible that under certain conditions, such as the presence of a colitis, that this phage may take on stronger properties and lyse not only the colon bacillus but dysentery bacilli and other organisms.

In order to test this hypothesis, in our recent colitis cases with a dysentery phage in the stool we set up this phage against the patient's own colon bacillus and against stock strains. Lysis did not occur. This would indicate that the bacteriophage is specific, at least in these cases, for the dysentery strains.

Therefore, we believe that a better conclusion would be both from Dr. Mackie's findings and our own studies, that when one finds an anti-dysentery bacteriophage in the stool of a non-specific ulcerative colitis patient that it should suggest the probability that that patient's disease is related to bacillary dysentery.

DR. JOHN L. KANTOR (New York City): I have nothing to add specifically to the technical points that have been brought out so conscientiously by the previous speakers. They have added several links to one aspect of the problem.

But I think we should continue to regard this question with a broadminded attitude. When several years ago the bacteriology was stressed as the solution of this problem, I pointed out, in discussion, what had been pointed out previously by Dr. Thomas Brown and many others, that other possibilities were still open, that for example the question of a metabolite circulating in the bodies of certain individuals and then causing damage to mucosa on its excretions was still to be considered. The same point was stressed by Dr. Necheles this morning.

May I call attention to the fact that certain bacteriologists are now engaged in the demonstration of the specific importance of the bacillary dysentery organism? Would it not be well for the Council to invite Dr. Felsen next year to produce evidence from the epidemiologic angle that ulcerative colitis may begin as a specific bacillary dysentery?

Briefly, he believes that bacillary dysentery is epidemic in this country and that the phase of specific infection is a very short-lived one, and that it is the rule for the bacteria to disappear from the stools in the first week or so and it is the exception to find them later. Repeated stool investigations, such as those that Dr. Mackie has so brilliantly performed, will give a fairly high incidence of dysentery "carriers."

We should also look to the psychologic make-up of these colitis patients. Dr. Sullivan last year pointed out something about their personality. I disagreed with one phase of his presentation as I understood it. It is nevertheless

a possibility that by psychologic tests we may be able to recognize certain individuals who are susceptible, either to their own metabolites or to specific germs that the rest of us throw off although we may be infected by them.

Dr. Lichtwitz, at the Montefiore Hospital, has been concerned about the metabolic aspect of these patients and has made some interesting observations. It is true that the altered metabolism is more likely to be a result than a cause of the disease, but we should learn about that also.

In other words, this Association shall keep an open mind as to the nature of this crippling disease and study it from all possible angles.

DR. BURRILL B. CROHN (New York City): It may be purely an accident that most of the speakers on this subject are from New York City. The interest in the relationship between bacillary dysentery and the so-called non-specific ulcerative colitis is still an open problem to all of us.

There is no question about the widespread distribution of bacillary dysentery throughout the country. The reason I stress New York City is because the Board of Health of New York City has notified us in a letter that in the year 1934 they had 365 cases of bacillary dysentery in Greater New York and in the year 1935, up to November, they had something like 590-odd cases.

In addition to that the files of the Public Health Service of the United States show bacillary dysentery prevalent throughout all the states of the United States. There are no states that are exempt. States like Massachusetts and Pennsylvania seem to have continuous case reports of bacillary dysentery.

Of course there is one criticism to all of these reports—*no one knows exactly what constitutes a diagnosis of* "bacillary dysentery." Nothing short of a definite finding in the stool of bacillus dysenteriae gives meaning to the agglutinins. We have obtained reports of agglutination reactions of from 1:160 or 1:180 or much higher, but what the significance of the specific agglutination means, is open to question. If the relibility and the pathological and normal limits of agglutination could be decided, and if a group of bacteriologists could determine what the agglutination significance is, then we could very soon determine what bacillary dysentery is and shortly we would know whether there is a relationship between bacillary dysentery and so-called non-specific ulcerative colitis.

DR. DONOVAN BROWNE (New Orleans, Louisiana): My knowledge and experience with bacteriophage is certainly inadequate. However, I have been impressed by the statements made by some of the discussants. First, that of accepting the isolation of a dysenteriae organisms from the feces of a patient as diagnostic of bacillary dysentery, and second the significance given an agglutination of 1 to 160.

About three years ago we made a rather careful survey in our particular section of the country, New Orleans. Groups were selected from various sections of the city which gave no history of dysentery or digestive disturbance. The feces were repeatedly cultured and the agglutinins in the blood for the dysenteric groups determined. That we were able to isolate one or more of the dysenteriae organisms in 8% of the normal individuals is very interesting. The most frequently encountered organism was the lactose fermenter of Duval. The bacillus of Shiga was rarely isolated but the most surprising feature of the study was the frequency with which the blood of normal individuals agglutinated stock cultures of *Bacillus dysenteriae*. This was particularly true of the less virulent groups such as the *meta dysenteriae* of Castallani and the Duval lactose fermenters. In certain instances, the normal blood titre ran as high as 1 to 300; this being so we are rather cautious in accepting agglutination of 1 to 160 as diagnostic of *B. dysenteriae*, except with the Shiga and possibly the Flexner groups, in which the agglutinins are apparently more specific.

The single isolation of an organism of the dysenteriae groups from the feces or obtaining a positive agglutination of stock culture of Bacillus dysenteriae in dilutions of 1 to 160 is not in all instances sufficient evidence to warrant a diagnosis of bacillary dysentery.

DR. T. T. MACKIE (closing the discussion): I shall go through the points that have been raised seriatem.

As is indicated by the title of our paper, the objective was an attempt to evaluate the significance of a lytic principle as a diagnostic measure pointing to present or *past contact of the individual with Shigella dysenteriae.*

In dealing with chronic infections, we have only three possible diagnostic measures available. One is the demonstration of the organism recovered from the patient's intestinal tract. The second is the demonstration of reacting substances in the patient's serum, which are generally accepted as evidence of a biologic association. The third is the so-called diagnostic bacteriophage.

I am in complete agreement with the view of the discussers that the significance of any given agglutinin titre is open to considerable question. Yet, when one is faced with the necessity of classifying cases, an arbitrary standard has to be accepted as a working basis. We originally chose the titre of 1 to 160, because of the experience of several British workers who have studied this question intensively.

The object of this paper was to raise a discussion not of the significance of the agglutination reaction in chronic bacillary dysentery, but of the specificity of anti-dysentery bacteriophage.

Certain Aspects of the Applied Physiology of External Pancreatic Secretion*†

By

A. C. IVY, Ph.D., M.D.

CHICAGO, ILLINOIS

EFFECTS OF EXCLUSION OF PANCREATIC JUICE FROM THE INTESTINE

DIGESTION and absorption: The most certain method for permanently excluding the pancreatic juice from the intestine in an animal is to tie the pancreatic ducts and then to separate the organ from all its connections with the duodenum (1-3). When this is done in the dog, one observes polyphagia, the passage of large bulky stools containing undigested and unabsorbed starch, protein and fat, and a gradual loss of weight in most instances unless special attention is given the diet.

The polyphagia is associated with a more rapid emptying of the stomach, which is probably a result of

*Delivered at the Thirty-ninth Annual Session of the American Gastroenterological Association, Atlantic City, N. J., May 4-5, 1936.

†From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago.

Approved by the Publications' Committee.

the partial starvation incident to defective intestinal digestion and absorption (4). The polyphagia is very obvious and persists indefinitely, for at least a year or longer (1-6). Associated with this a hypernormal secretion of gastric juice may occur (4). A hyponormal secretion has not been observed experimentally except in poorly nourished animals. A detectible compensatory increase in the secretion of enzymes in the *succus entericus* does not occur (7).

The passage of bulky stools is observed early, provided post-operative complications, which cause anorrhexia, are absent. The stools (dry weight) as a rule are more bulky than those of obstructive jaundice (1-4) or sprue (1). The digestion and absorption of protein are affected slightly more than that of fat, that of carbohydrates being least affected (6). The deficiency varies considerably in different animals and to an appreciable extent in the same animal, the cause of the variation being unknown. I suspect the variations are due to differences in the emptying time of the intestine ("intestinal time"). On increasing the quantity of food, total absorption is increased, but the efficiency of absorption is diminished (6). Some dogs with exclusion of pancreatic juice from the intestine withstand the deficiency when fed an average stock diet much better than others (1-6). Unless some special attention is given the diet, the majority lose weight progressively. More recent observers find that if raw pancreas is added to the diet nutrition may be maintained for more than a year. We (2,3) have maintained six animals in an excellent condition for more than a year, by feeding 200 gm. of raw ground pancreas daily. The same is true of the majority of depancreatized dogs. Yet, an occasional depancreatized dog may be maintained in a good condition on insulin without receiving pancreas for a year or more (8, 9), if given a high vitamine diet. Handelsman, Golden and Pratt (6) studied three dogs with exclusion of pancreatic juice. All three animals received a diet containing a liberal amount of carbohydrates and milk fat. The one not receiving brewer's yeast died in three months of inanition. The two receiving the same diet, plus yeast, lived in good condition for eight months and two years, respectively.

We (10, 11) have observed more than one hundred dogs in which the pancreatic juice and bile are emptied into the last six inches of the ileum. These dogs suffer from a deficiency of intestinal digestion and more than 90% of them lose weight. The administration of raw pancreas and gastric mucin definitely improved the nutrition of 40% of twenty such dogs. The feeding of a special diet high in nuclear substances, vitamines, milk fat, and readily assimilable carbohydrates maintained the nutrition of 60% of the dogs, for 10 weeks or longer, or until they developed jejunal ulcer. This special diet fed to similarly operated dogs, which had in addition from two-thirds to three-fourths of the fundus of the stomach removed, thus suffering from a deficiency of both pancreatic and gastric digestion, 51% of thirteen dogs remained in excellent condition for more than one year, and six of the thirteen remained in excellent condition for more than two years.

The special diet consisted of:

A prepared stock dog food		400 grams
Percentage composition		
Cooked wheat and barley flour	75%	
Dried milk	10%	
Tomatoes	5%	
Bone meal	5%	
Cod liver oil	5%	
Fresh whole milk		200 grams
Raw ground pancreas		300 grams
Raw ground liver		200 grams
Corn syrup		100 grams
Banana flour		50 grams
Total		1250 grams

The dogs were fed all of this diet they would ingest, and some dogs ate as much as from four to six pounds daily. The fecal wastage was obviously very high.

We agree with Pratt and others that patients affected with pancreatic deficiency should receive a liberal diet, high in easily assimilable carbohydrates and emulsified fat (milk), enough protein being fed so that sufficient is absorbed to maintain a positive nitrogen balance. Fats with lower melting points are somewhat better digested than are those with higher melting points, probably because of easier emulsification (12).

Oral enzyme therapy in pancreatic deficiency: The effectiveness of orally administered pancreatic enzymes has not received general acceptance, because doubt exists as to whether they may pass through the stomach without being inactivated.

Prior to 1912 the literature (13) contained a few carefully studied patients who exhibited pancreatic deficiency, in whom the administration of raw pancreas and pancreatin decreased the fecal loss of fat and nitrogen. Very little clinical investigation has been reported since then. However, in 1925, Silverman, Denis and Leche (14) studied the effect of oral administration of pancreatin and raw ground pancreas on the duodenal concentration of enzymes in a human subject. Their results showed that pancreatic preparations taken by mouth enhance the digestive power of duodenal contents. We (2) have recently found, in a study of the effect of the oral administration of malt amylase to ten human subjects, that when it is mixed with a cereal meal an average of 51% of the enzyme passes into the intestine before it is inactivated. The gastric digestion of starch is also appreciably augmented. Malt amylase was used because it is inactivated at a lower pH than salivary or pancreatic amylase.

Experimentally raw pancreas has been added to the diet of depancreatized dogs because of its enzyme content. However, very little work has been done to ascertain if it is really effective in this regard. Pratt, Lamson and Marks (1) fed pancreatin to two dogs (9.6 gm. and 18.0 gm. daily) with a separated pancreas and observed a decrease in the nitrogen and fat lost in the stools. Nasset, Pierce and Murlin (15) fed pancreas (10-20 gm. daily) to two depancreatized dogs and observed an increase in nitrogen absorption.

To determine how effective taka-diastase and malt amylase are when given orally, we (Schmidt, Beazell and Ivy) have separated the pancreas from the duodenum in five dogs, placed them on a high cereal (82% farina) diet, containing 62% starch, and after suitable control periods have fed the enzymes, the starch loss in the feces being followed by a quantitative method. The

average starch loss during the control period was 24.2% in five dogs. The administration of malt amylase (35 gm. daily; 50 gm. of Ovaltine, having a U. S. P. potency or slightly higher) daily reduced the average starch loss to 14.0%. Taka-diastase (25 gm.; U. S. P. potency or slightly higher) reduced the average starch loss in three dogs from an average control loss of 27.4% to an average of 15.6%. The dry weight of the feces was also decreased.

Thus, there can be little doubt as to the oral effectiveness of enzymes administered in the presence of pancreatic deficiency. We (2) have shown that it is best to give some enzyme with the meal and then some in water just after the meal. Pancreatic enzymes might also be given between meals, if given in some buffered solution as milk to buffer the acid in the stomach.

Liver: In connection with the exclusion of pancreatic juice from the intestine, it is important to bear in mind that depancreatized dogs receiving only insulin are very prone to develop hepatic insufficiency due to infiltration of the liver with fat. This is prevented by feeding raw pancreas, lecithin or choline (for references see ref. 13). Whether fatty infiltration and degeneration of the liver occurs when the pancreas atrophies as a result of fibrosis or obstruction of the ducts has not been demonstrated to my knowledge. Yet, the implied importance of administering lecithin containing foods to patients suffering from pancreatic deficiency should be remembered.

We (16) have recently found that within three weeks after ligation of the pancreatic ducts, or separation of the pancreas from the intestine, the capacity of the liver to form sugar from protein (gluconeogenesis) is impaired.

Berg and Tucker (17, 18) observed morphologic liver changes to occur from two to three weeks after duct ligation or pancreatectomy, and sooner when all the pancreatic juice was drained externally.

BLOOD ENZYMES AND EXCLUSION OF PANCREATIC JUICE

Amylase and lipase: It is established that obstruction of the pancreatic ducts or any disturbance which causes a passage of pancreatic enzymes into the blood and lymph results in a marked rise in serum amylase (liquefying) and lipase (emulsified-oil-splitting). The marked rise lasts for a few days only, some animals possibly showing slight rises from time to time for a longer period (1 or 2 months). Rises in serum lipase and amylase also occur in liver disease, but the rises observed are slight in comparison to those of acute pancreatic disease.

It would appear that only the visocometric or starch-iodine methods (Wohlgemuth), which detect the early stages of the hydrolysis of starch (liquefying), should be employed to test for serum amylase in pancreatic disease. This is because Reid and Narayana (21) found no increase when using reducing sugar methods (saccharogenic amylase) (22). In pancreatic disease, emulsified-oil-splitting lipase should be determined; a serum esterase determination by the ethyl-butyrate method has no significance (19).

Serum phosphotase is very high in obstructive jaundise in man and dog (23-26). It is also elevated markedly in catarrhal jaundice (24). Freeman and Ivy (23) have found it to be markedly elevated when only one hepatic duct is obstructed (33% of liver tissue) and the icteric index normal. We have also found that ligation of the pancreatic ducts or separation of the pancreas from the intestine causes only a slight temporary rise in serum phosphotase.

Thus, it is possible to diagnose acute involvement of the pancreas in the presence of obstructive jaundice. If serum amylase, lipase and phosphotase are all high, the liver and pancreas are both obstructed. If the phosphotase is very high and the amylase and lipase only slightly elevated, the liver is involved and the pancreas only slightly, if at all. If serum amylase and lipase are high and phosphotase low, the pancreas is more acutely involved than the liver.

However, it must be remembered that serum phosphotase remains high as long as hepatic obstruction persists and that serum amylase and lipase are high only for a relatively short period after obstruction of the pancreas. Hence, in chronic pancreatitis, a determination of serum enzymes is of little value, and one must rely on the results of the examination of either the duodenal contents or the stools.

FUNCTIONAL TESTS OF EXTERNAL SECRETORY ACTIVITY OF PANCREAS

I suspect that a deficiency of external pancreatic secretion occurs more frequently in man than is now believed. The pancreas appears to be less influenced by secretory nerves and nervous states than the stomach. Yet, its enzyme output is thought to be controlled more by nerves than by the hormone secretin. The hormone causes a copious flow of a thin secretion relatively low in enzyme concentration, although in man and dogs we (27) have observed an increase in total output of enzymes. However, the secretion of the pancreas is markedly reduced by very small amounts of epinephrine (28); and if the discharge of epinephrine by the adrenals is augmented sufficiently by emotion or anxiety, we should expect pancreatic secretion to be reduced. It would also be reduced by excessive splanchnic vasoconstriction.

In regard to functional tests, the question of the *factor of safety* of the organ deserves first consideration, because the factor of safety must first be destroyed before most functional tests show the presence of a deficiency. Very little work has been done on the factor of safety of the acinar tissue of the pancreas. We (28) have studied the response of the pancreas to secretin after excision of various parts. Excision of only a small portion of the tail or head of the pancreas results in a definite decrease in response. Thus, when secretin is the stimulant, the response is directly proportional to the amount of acinar tissue. We found further that functional regeneration of acinar tissue does not occur within two months. This is in contrast to the stomach in which organ excision of two-thirds of the fundus decreases the response to histamine and later the fundus hypertrophies (three to six months) and a normal response to histamine is obtained.

Destruction of acinar tissue only reduces the total capacity of the gland to secrete to a stimulus, and this can happen without a reduction of the enzyme concentration. So, on analyzing duodenal drainage in chronic pancreatitis, one must consider the factor of dilution of the pancreatic secretion, which as secreted may have a normal concentration of enzymes, by bile, duodenal juice and gastric fluid (the latter can be ruled out by testing the reaction of each ten minute specimens and discarding them if acid or only slightly alka-

line, or by draining the stomach with a second tube). Because of the dilution factor, we have never placed much emphasis on the concentration of enzymes in duodenal drainage, and have placed emphasis on the total output of enzymes over a period of time. However, we believe that the absence of, or the existence of, a markedly reduced enzyme concentration in duodenal drainage, the drainage being alkaline (pH 7.5 to 8.0), especially after stimulation, is significant. But, we do not believe a normal concentration or only a slightly reduced concentration is significant. In this connection I personally consider many of the findings of McClure and his colleagues, and of others, as significant.

Most of the foregoing data and discussion, however, is obviously not applicable to the question of how much of the acinar tissue of the pancreas has to be destroyed in order to obtain defective digestion and absorption of food. The data and discussion is not applicable, because we know that considerable digestion and absorption occurs when all the pancreatic juice is excluded from the intestine. Oddly this question has not been studied by direct experimentation with the employment of adequate methods. That is, no one has fed a standard test-meal and then extirpated portions of the pancreas to ascertain the amount that must be removed to cause fecal wastage. With the data available on the effect of complete exclusion and considering the apparent fact that the capacity of the pancreas to secrete is directly proportional to the amount of acinar tissue, one may make theoretical predictions. On the average carbohydrate diet in the dog, approximately 90% of the pancreatic amylase secreting tissue would have to be removed before starch would appear in the feces. On a high cereal diet (62% starch) approximately 66% of the pancreas must be removed. On an average fat diet, about 66% must be removed; on a high fat diet, about 50% must be removed. On an average protein diet, about 55% must be removed; on a high protein diet, about 40%.

Whether one may obtain more reliable data for practical purposes by examination of the feces than by duodenal drainage, I believe is an open question. Several years ago we (27) injected secretin intravenously into twenty-two presumably normal medical students with a duodenal tube in place. We found that some individuals may manifest a low secretion of one enzyme and not the others. The secretion of trypsin was most uniform. Amylopsin was most easily exhausted apparently, but lipase was more consistently low than the other enzymes. In two subjects the lipase was so low as to appear to be abnormal. So, these two subjects were fed a meal consisting chiefly of one-half pound of rare beef and 60 c.c. of olive oil. Both subjects manifested steatorrhoea, but not creatorrhoea.

I suspect that secretin may be found to have the same relative merits in a test of pancreatic secretory function that histamine has in a test of gastric secretory function. It should be obvious, however, that the results of a secretin test or of duodenal-drainage analysis may not be a test of the efficiency of intestinal digestion, because, although pancreatic juice plays a very important *rôle*, other factors are concerned such as the quantity and quality of intestinal juice and bile, and intestinal time or motility, and the normality of the absorptive process. Fecal analysis can be the only practical and reliable method for testing the efficiency of intestinal digestion.

Some day a dye may be discovered which will be specifically eliminated by the pancreas and which will provide us with information concerning the volume output of secretion, but more than one hundred dyes have been examined in my laboratory and none found to be of practical worth.

As a standard test-diet for the study of digestion and absorption in pancreatic and intestinal disease, that of Adolph Schmidt (21, 1) should be mentioned. Space does not permit its discussion.

PANCREATIC SECRETION IN JAUNDICE

It has been suggested (30) that the cause of the soapy stool in jaundice is due to a failure of the pancreas to be stimulated because bile is "the alimentary stimulus for pancreatic secretion." While it is true that bile of proper reaction in the duodenum stimulates the pancreas, it has been shown that either common duct obstruction (31) or the drainage of all bile to the exterior (32) does not reduce the secretion of the pancreas. Thus, the soapy or fatty stool of jaundice is not due, as chemical analyses confirm, to disturbed pancreatic digestion but due to *disturbed absorption*. The disturbance of absorption is due to the absence of the important *rôle* that bile salts play in rendering fatty acids soluble in aqueous solution at the slight acid reaction commonly found in the intestine.

FOODS AND PANCREATIC SECRETION

In providing nourishment to patients having pancreatic fistulae, subacute or non-fatal acute pancreatitis, or in which the pancreatic juice has been excluded from the intestine as in the Whipple operation for carcinoma of the head of the pancreas, it is important not to give foods which stimulate pancreatic secretion. In acute pancreatitis patients should not be fed orally, as a matter of fact it is usually impossible because of vomiting and collapse.

Glucose intravenously does not stimulate the pancreas (36), neither does saline solution, in my experience, unless given in quantities sufficient to cause a hydremic plethora. All agree that taking most any substance by mouth with the exception of alkalies stimulates pancreatic secretion. I teach that foods which stimulate the formation of gastric juice and cause the gall bladder to contract are those which in general stimulate the pancreas most. According to Pavlov meat and bread are about equally potent, and fats and milk rank second. Acids such as found in gastric juice and fruit juices stimulate. Water stimulates and alkalies decrease (33, 34, 37). My own experiments would cause me to list the foods in order of potency as follows: meat, first; milk and fats, second; white bread and carbohydrates, third (38, 39). Wohlgemuth (34) and Holsti (35) rank carbohydrate first. Wohlgemuth introduced a low carbohydrate diet (antidiabetic) with large amounts of sodium bicarbonate for the treatment of pancreatic fistula. Some have obtained good results, others bad. It is my opinion that we do not know which foods stimulate the pancreas most or least, or whether foods have a specific effect on enzyme content of pancreatic juice as claimed by Pavlov. I believe a statistical study is required to settle this matter because of the variations reported.

(For a review of human pancreatic fistula cases see ref. 40).

Time and space do not permit a discussion of such topics as: (a) the effects of loss to the outside of pancreatic juice, (b) the decrease sugar tolerance found in pancreatitis, (c) the *rôle* played by pancreatic juice *vs.* bile in the development of "peptic ulcer," (d) the *rôle* of pancreatic secretion in the regulation of the reaction of the stomach, intestine and blood; (e) fat necrosis; (f) etiology of pancreatitis; (g) pain in pancreatic disease; and (h) pancreatic secretion in sprue and coeliac disease.

DISCUSSION

DR. JOSEPH H. PRATT (Boston, Massachusetts): We have been able to produce experimental acute pancreatitis in dogs without the introduction of bile, intestinal juice or stomach contents. This has been accomplished by simply tying the pancreatic ducts and separating the pancreas from the duodenum by the insertion of the omentum between the two. This procedure was devised by Dr. Fred T. Murphy, as Dr. Ivy has stated, for shutting out all pancreatic juice from the intestine. In a considerable proportion of animals on which this operation was performed fatal acute pancreatic necrosis developed with the death of the animal in two or three days.

The claim has been made by a number of German writers, chiefly surgeons, that the presence of a pancreatic lipase in the blood is diagnostic of acute pancreatitis, and that the lipase is also increased in cancer of the pancreas. In several of our dogs with occluded pancreatic ducts the atoxyl-resisting lipase was determined in the blood and no significant increase found.

In 39 cases of various diseases Dr. Magendantz of our staff determined the amount of pancreatic lipase by the stactometric method of Rona and Michaelis. In this series there was no case of acute pancreatic necrosis but four of cancer of the pancreas. In none of these was the atoxyl-resisting lipase present in a significant amount. On the other hand a relatively large amount of this lipase was present in other diseases, namely, abscess of the liver and obstructive jaundice. An increase was also present in syphilis and in angina pectoris uncomplicated by abdominal disease. In the method we used the splitting of tributyrin was measured. Crandall and Cherry found in the blood a lipase capable of splitting a true fat (olive oil) after the pancreatic ducts were tied. We hope to use their method in further experiments.

Golden and others in our laboratory have determined the amount of diastase in the blood in ten dogs after occluding the pancreatic ducts. The improved method of Wohlgemuth was used. Previous to the operation 2 to 64 units of diastase were present in the blood. Twenty-four hours after the pancreas was separated from the duodenum the diastase increased in the blood of all the dogs. The smallest rise was to 256 units, the average over 500, and the largest 2048 units. The diastase curve usually reached its highest point on the second or third day after the operation. When obstruction of the ducts was permanent the amount of diastase usually remained above the normal level. In one dog 825 days after the operation 256 units were still present. If the obstruction is overcome by the formation of sinuses the level of blood diastase quickly drops to normal. Our results show that if there is obstruction of the pancreatic ducts the blood diastase will rise. From the experiments the conclusion cannot be drawn that in acute pancreatitis the blood diastase will be high. If an increase is found in acute pancreatitis it is, I believe, evidence of a retention of pancreatic juice within the ducts. In a case of cyst of the pancreas Dr. Golden found a large amount of diastase in the blood.

Dr. Ivy is correct in his statement that total obstruction of both pancreatic ducts is rarely seen clinically. When it does occur it is characterized by the passage of bulky stools

while the patient is on a full diet. I am sorry that the use of the Schmidt diet seems to be out of fashion. When it is employed much can be learned in the diagnosis of pancreatic disease from the gross and microscopic study of the stools. When no pancreatic juice enters the intestine the weight of the dried stools is greater than in any other condition. With normal digestion Schmidt found that the average weight of the dried feces during a period of three days on his diet averaged 54 grams. In a case of obstructive jaundice we found that the weight of the dried feces during three days on the Schmidt diet was 131 grams, while in four cases of total occlusion of the pancreatic ducts the weight was over 400 grams.

The chemical analysis of the stools is very time consuming and requires a skilled worker. In the recognization of occlusion of the pancreatic ducts I urge the value of the simple procedure of determining the weight of the dried stools. If Schmidt's standard diet is used for a three days' period it will be possbile to compare the results obtained with those of Schmidt and other workers. If the weight of the dried feces is 300 grams or more it is almost conclusive evidence of total obstruction of the pancreatic ducts.

DR. JULIUS FRIEDENWALD (Baltimore, Maryland): I should like to direct attention to the cases of pancreatic diseases reported some years back by Doctor Cullen and myself. Of these there were four instances of acute pancreatitis, fifteen of chronic pancreatitis, seven of pancreatic cysts and thirty-seven of carcinoma.

In all of the acute pancreatic cases, the patients had been affected with previous attacks of indigestion complicated by the presence of gall stones and biliary colic. The attacks began with sudden violent abdominal pain referred to the epigastrium. Diabetes was present in one patient, in another there was a subsequent abscess formation. Fat necrosis occurred in all. Three of the patients recovered following operation; one died.

In the cases of chronic pancreatitis the symptoms were indefinite but this disease may be suspected if in a patient having chronic dyspepsia there is present epigastric pain often to the left of the mid-line and not infrequently referred to the left shoulder blade associated with nausea, vomiting, emaciation, weakness and slight jaundice. In more advanced cases, intermittent glycosuria, hyperglycemia, bulky soft fetid stools aid in arriving at the diagnosis. In our cases of chronic pancreatitis there was a history of chronic indigestion in eleven and biliary colic in five. Our greatest aid in the diagnosis is derived from the examination of the duodenal contents for pancreatic ferments, the activity of which is markedly diminished in this affection.

In our cases of pancreatic cysts there was present a prolonged history of indigestion and abdominal discomfort with colicky pain; as the cyst enlarges the pain becomes pronounced. The pain may be located in the epigastrium but is often referred to the back or may be in the right or left hypochondrium. The most distinctive sign in our cases was the progressive enlargement of the tumor between the xyphoid cartilage and the umbilicus. The mass produced a protrusion in the median line but most frequently in the left hypochondrium.

In the diagnosis of carcinoma of the pancreas as we have found the following associated signs and symptoms of importance: (1) Digestive disturbances, (2) presence of a tumor and the enlargement of the gall bladder, (3) symptoms produced by involvement of the pancreas itself and by pressure of the growth upon neighboring organs.

It is of interest to note, that at times when operating fór gall stones, the surgeon may discover a large hard and often nodular mass in the region of the head of the pancreas which may lead to the diagnosis of cancer. His diagnosis may be incorrect; the hard nodular mass may be due to a chronic pancreatitis. In a small group of cases, however, the very reverse is true, the mass may be considered in the light of a chronic pancreatitis when it may finally be proven to be cancerous.

Attention is directed to a small though definite group of cases in which according to our experience the definite signs are preceded by a persistent diarrhea. The patient may at times complain of loss of appetite, nausea and vomiting but without pain. Constipation which is usually present at first is rapidly transformed into a diarrhea which becomes more and more excessive and finally fatty stools appear. After a shorter or longer period of time jaundice manifests itself which gradually becomes more and more pronounced. This symptomatology occurs frequently enough to warrant the conclusion that whenever a persistent diarrhea is observed in individuals during or past middle life which cannot be accounted for by the usual causes, carcinoma of the pancreas should be suspected.

DR. THOMAS R. BROWN (closing the discussion): I should like to say just a few words. First, I want to reiterate the importance of the abdominal symptom upon which Dr. Jones has touched, that is the presence of deep abdominal pain in the left hypochondrium at about the level of the gall bladder, sometimes associated with deep tenderness in this region. And second, that we must not forget it is essential to study the stool from every angle as it may give us clues which we constantly miss if we fail to carry out this procedure.

Diseases of the Pancreas -- The Clinical Aspect*

By

THOMAS R. BROWN, M.D.†

BALTIMORE, MARYLAND

THE pancreas is a much neglected organ. When one realizes the enormous *rôle* played by the external secretion of the pancreas in the digestion of all the foodstuffs and its close relationship—geographical, vascular, lymphatic, nervous — with stomach, duodenum, gall bladder and transverse colon, all organs in which a great deal of pathology is found and diagnosed, we must conclude either that the pancreas is an organ singularly immune to disease or that in the majority of cases we do not recognize its pathology, organic or functional.

I am sure the latter is true. I am quite sure a considerable number of vague upper abdominal syndromes,

*Delivered at the Thirty-ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1926.

†Chief of the Division of Digestive Diseases, the Johns Hopkins Hospital and the Johns Hopkins Medical School.

Approved by the Publications' Committee.

sometimes only with gas, distension and discomfort, sometimes also with true pain, are due to this cause, especially in older people where the chances of infection, vascular change and sclerosis are of course obviously increased.

One has many reasons for this belief. First, the number of cases in which changes in the pancreas are found when the abdomen is opened for other causes and where the surgeon finds an unsuspected pancreatitis, sometimes the only finding, and therefore the obvious cause of the symptoms that no one had suspected were pancreatic in origin; second, though this of course is much less frequent, the times when we find evidence of fat necrosis when the abdomen is opened, obviously representing the aftermath of a previous and unrecognized acute or subacute pancreatitis; and third, the fact that the pancreas is supplied with autonomic nerves and that these are susceptible to the same disturbances met with in any other portion of the sympathetic system—local, reflex or psychogenic in origin.

There is of course definite experimental evidence in favor of this, for although Starling and Bayliss feel that in explaining pancreatic secretion, the mechanism of a special hormone could explain the whole phenomenon, this obviously cannot be true. In the first place, Pavlov, Koschinsky, and many others have shown that by stimulating the pancreatic nerves, a definite pancreatic secretion is brought about. In the second place, it can be shown in experimental animals that severe shock can produce a complete pancreatic achylia. Finally, the fact that in true gastric achylias, when no hydrochloric acid whatsoever is found and when therefore the normal mode of stimulation of changing prosecretin into secretin is absent, the pancreatic secretion may be, and usually is, absolutely normal. In these cases this must be brought about by nervous, not chemical, stimuli. We have found this to be true, for instance, in cases of pernicious anemia and various other conditions where a complete gastric achylia is shown by histamin stimulation and fractional meals. We have made these tests both by the study of duodenal contents and the more accurate, if properly done, though much more difficult quantitative estimation of the pancreatic ferments in the stool.

What do we diagnose sometimes correctly — and sometimes incorrectly? The relative parities — pancreatic cyst, pancreatic carcinoma, acute pancreatitis. What do we almost always fail to diagnose? Practically all cases of the much more common chronic and mild subacute pancreatitis, and, in all probability, the major proportion of the functional disturbances.

As to *pancreatic cysts*—degenerative, traumatic, inflammatory—and pseudo cysts—round or oval tumors, usually in the midline just about or above the umbilical region, usually increasing, though slowly, in size, occasionally fluctuating, more often tense, with occasional spontaneous changes in size—this is the usual picture to be differentiated from mesenteric or retroperitoneal cysts or even solid tumors in this area, and of course to be treated surgically with marsupialization.

Pancreatic carcinoma is most frequently found in the head of the organ, with the classical picture of progressive painless jaundice, rarely a palpable tumor in the earlier stages at least, usually associated with an enlarged gall blader with the usual general symptoms of any form of malignant neoplasm—progressive loss of weight and strength, occasionally with symptoms very suggestive of carcinoma of the transverse colon. And yet not always this classical picture for the growth is not always in the head of the pancreas and jaundice may be absent. It is not always painless as in some cases pain, especially severe left back pain, is common even in the early stages of the disease, though of course much more frequent later when it may be very severe. The gall bladder is not always enlarged for its walls may be so thickened by the chronic cholecystitis, with or without stones, which is so frequently associated with pancreatic disease, that distension is impossible.

And again, the classical picture may be absolutely simulated by painless *common duct stone* or by *cirrhosis of the head of the pancreas*. In the former case the true diagnosis may sometimes be suspected by noting periods where the jaundice is lessened, associated with a slight transient pigmentation of the stool. In the latter case, even the surgeon is frequently unable to make a differential diagnosis at the time of the operation, usually a cholecystgastrostomy, and only time can answer the question—in the one case, death, albeit a bit belated; in the other, progressive improvement and return to health.

Unquestionably there is frequently a disappearance of the pancreatic ferments in duodenal contents or in stool—the bulky stool—in cases of carcinoma of the head of the pancreas. How much of this is due to destruction or dysfunction of the glandular tissue due to the disease, how much is due to a complete obstruction to the pancreatic duct, how much to the associated chronic and progressive jaundice with its increasingly inhibitory effect upon glandular secretion, is hard to say. I believe, however, the obstructive factor is the largest factor as I have seen a few cases of carcinoma of the pancreas without obstruction to the common duct and without jaundice, in which the pancreatic ferment readings were quite normal. It is very probable that the pancreas, like the liver and possibly many other organs, has a large margin of reserve and can produce a practically normal secretion even where there is considerable destruction of certain portions of its substance as in carcinoma.

If one wishes to visualize every phase of the progressive downhill course of carcinoma of the head of the pancreas in its classical form, may I recommend a novel by the great French physician-novelist, Paul Bourget, "The Night Cometh."

Acute hemorrhagic pancreatitis, one of the acute abdominal catastrophies, presents in its earlier phases at least a picture far more suggestive of a profound toxemia than of an infection or inflammation: exquisite epigastric pain and tenderness with very little muscle spasm, profound prostration and shock, circulatory collapse with thready pulse, little or no increase of temperature or white blood count at first—somewhat suggestive of high ileus. Of course when the inevitable inflammation and infection set in, the picture changes and the condition is therefore frequently diagnosed as perforated gastric ulcer, severe gall stone colic, perforation of the gall bladder or high intestinal obstruction.

And yet the picture rarely lacks some suggestive diagnostic sign or symptom if we but search carefully for it, especially if the patient has given a previous history of gall bladder disease, which is so frequently associated with this condition. Although usually occurring in people of middle or later life, it is occasion-

ally met with in very young children. It practically never occurs in those whose gall bladders have been previously removed. The cause may be the rare trauma, the commoner infection, possibly some other factor, the infection arising usually from a diseased biliary tree, possibly with an increase of biliary pressure. Many have believed that the infected material is retrojected directly into the pancreatic ducts and canaliculi. The recent work or Rich, however, shows that the biliary pressure under no condition becomes so high as that in the pancreatic secretory system, makes this method of infection much less probable. Infection, therefore, if it plays a *rôle*, takes place probably directly through the lymphatic system.

But whatever the cause, the effect is the same—trypsin zymogen is activated, autolysis takes place, and a group of toxins of extreme potency is elaborated; toxins peculiarly affecting the circulatory apparatus—hence the extreme vascular collapse so characteristic of the disease.

Rich also has shown that there occurs a constant and specific vascular lesion with rapid necrosis of the walls of arteries and veins—the direct result of the action of the trypsin upon them, and that the pancreatic hemorrhage results from the rupture of these necrotic vessels. He shows too, that the majority of cases result from potential obstruction to the outflow of the secretion in the smaller ducts, that this obstruction is usually due to metaplasia of the epithelium and that attacks are peculiarly likely to occur after a large meal or after alcohol.

If the disease is recognized and surgery performed—that is, drainage of the destructive ferments or cholecystectomy—some cases die, some get well. If operation is not performed, perhaps because the condition is not recognized, perhaps because it is not of extreme severity, perhaps because some surgeons believe that nature, not the knife, gives better results, some recover with extensive areas of fat necrosis; a few, a very few, develop suppuration and gangrene with that remarkable picture — a pancreatic abscess, a tumor, steadily increasing in size and when opened showing bits of necrotic pancreatic tissue floating in the pus. It is extremely uncommon and rarely diagnosed correctly. Dr. Halstead once said that he should like, above everything, to make such a diagnosis before he died, but his wish was not gratified. He saw only two cases, in neither was pancreatic disease suspected and the true pathology only determined by the exploratory operation.

Pancreatic calculus is extremely uncommon and rarely diagnosed correctly, the attacks of pain almost exactly simulating those of gall stone colic without jaundice. If the condition is suspected, however, the diagnosis may possibly be made by stool and urine studies, there being an absence or marked diminution of pancreatic ferments in the former and an enormous increase in the latter. We established this urinary normal of diastase in 1914 and in the one case of pancreatic stone we have diagnosed, the amount of urinary diastase was increased more than twenty times. Incidentally, the quantitative estimation of diastase in the urine is a good test of renal function except, of course, in those cases where there is jaundice or obvious pancreatic disease, and the readings run practically parallel with the phenosulphonphthalein readings, as Rowntree and I found in that same year.

Chronic pancreatitis rarely is diagnosed but I believe is frequently present. I am quite sure that some of the vague upper abdominal syndromes met with in people of middle or later life are of this origin. The condition probably represents either a sclerosis or a low grade of infection originating from a diseased gall bladder.

Unquestionably the most common source—is gastritis, a duodenitis, possibly from the large bowel. In most cases it is probably through the lymphatic channels. But it may occasionally represent a direct extension from disease in the vicinity, such as peptic ulcer or cholecystitis. All of us of course have seen definite cases of perforation of peptic ulcer into the substance of the pancreas. Sometimes a suspicion of pancreatitis may be made more probable by certain laboratory findings—an alimentary glycosuria, changes in the stool, preferably with the patient on a Schmidt diet, with abnormal amounts of undigested fats or starch or meat fibres. Sometimes a real azotorrhea, sometimes a true butter stool with more than one-half the ingested fat unabsorbed and of this, 50% or 60% in the form of neutral fat.

Certainly marked disturbance in fat digestion, the absence of jaundice, diarrhea, is very suggestive of pancreatic disease, because almost all of the fat splitting ferment is found in the pancreatic secretion, only minimal amounts in gastric contents or in intestinal juice. Some have lain stress upon the presence of undigested nuclei in the stool if bits of thymus or muscle fibre are given by mouth, as the pancreas is the main, if not the only, source of nuclease.

But none of these tests is absolutely diagnostic because we always have a number of variables—differences in the motor and absorptive powers of the intestine, the possibility of vicarious enzymes from other sources and possibly the effect of enzymes of bacterial origin, to confuse the picture.

We have found a considerable diminution, though not complete absence of pancreatic ferments in the stool or duodenal contents, of help. In the case of diastase, for instance where by our method the readings for normal individuals vary between 600 and 2400 starch gram units, our figures ran between 120 to 300 units in cases of definite chronic pancreatitis. We know, of course, from definite animal experiments that there is a definite quantitative and possibly qualitative response of the pancreatic secretions to food. Obviously we cannot study our cases from pancreatic fistula as we can in animals, hence there are many possible errors in the estimation of these ferments in both duodenal contents and stool. Nevertheless, I believe the results obtained thereby are of real value, especially in the case of diastase and trypsin, if all sources of error are reduced to an "irreducible" minimum and the most meticulous care employed in carrying out every test.

With the possibility of pancreatitis in our minds, with the careful analysis of symptoms and with the use of some or all of these laboratory tests, I feel that pancreatitis can probably, if not absolutely, be diagnosed in many more cases than obtains at present. I am equally sure that, just as in the evolution of cirrhosis of the liver, we may have attacks of pain sometimes so severe as to simulate gall stone colic, yet entirely of inflammatory origin and probably due to acute exacerbations of the infectious process, so in the pancreas we may find a similar picture—pain, sometimes severe pain, which suggests obstruction of some kind

but which in reality probably represents a small acute transient process in the course of the slowly progressing degenerative, sclerotic or infectious process which is called "chronic pancreatitis."

As regards treatment, pancreatic ferments by mouth, the minimizing of infection elsewhere and the proper diet, especially one limited as to fats, unquestionably help certain of these cases. I have always felt in this connection, that it is probable that in certain cases of cholecystitis, with or without stones, the benefit that follows from a fat low or fat free diet is not all due to its effect upon the biliary infection, but is rather due to the effect of this diet upon the associated pancreatic disease or dysfunction so frequently associated with gall bladder disease. In my experience, if gall bladder disease, even cholelithiasis, is not associated with jaundice or pancreatic trouble, the simpler fats, butter, cream, olive oil and especially egg yolk are in reality our most valuable dietetic aids in promating gall bladder drainage and should be used in large amounts.

Are there *functional disturbances* of the pancreatic external secretion? There must be, for the pancreas is supplied with autonomic nerves which unquestionably play some, if not the major, *rôle* in stimulating or inhibiting secretory activity and therefore there certainly must be examples of hypo-, hyper-, and achylia-pancreatica of this origin. But its diagnosis is obviously extremely difficult; probably in most cases impossible, for while we may suspect it, it is very hard to differentiate from mild chronic pancreatitis, just as it is equally difficult or impossible to differentiate certain functional gastric disturbances from a mild gastritis, although the gastroscope may settle this question.

I have seen a few cases, however, in which I think the diagnosis was absolutely justified. Let me report one—a woman who had been operated upon many years ago and eighteen gall stones removed from the gall bladder. When seen by me fourteen years later, she had definite recurrent gall stones attacks and I had her operated upon with a removal of the gall bladder filled with stones. The pancreas was found perfectly normal at the time but a few days after the operation she developed an intractable diarrhea with typical butter stool and complete absence of pancreatic diastase and trypsin. Time, diet, possibly helped by the administration of pancreatic extract in large amounts, cleared up the condition; in a relatively short period of time, the diarrhea stopped, the stool regained its normal character. That the pancreatic trouble was purely functional, I think was shown beyond question not only by the rapid return to normal of the stool and the reappearance of pancreatic ferments in the fecal material, but by the fact that in a subsequent operation made about three months later for adhesions, the pancreas was examined carefully and found to be just as normal as it had been at the time of the preceding operation. If diarrhea follows cholecystectomy, as it does in a very small proportion of cases, it is probably often of this origin.

In thinking over the problems of the pancreas, one cannot fail to ask himself certain questions not answered in this rapid survey of our experience in this field. The most important is—is the pancreas an absolutely essential organ? Apparently not as regards its external secretion for proteolysis can be brought about by the pepsin and hydrochloric acid of the stomach, the erepsin, and possibly other ferments of the small intestine, and possibly by bacterial action. There is diastase from the salivary glands with minimal amounts from Brunner's glands and the bile to carry on starch digestion. The fats, however, will fare rather badly for lipase is derived almost exclusively from this organ and fat digestion is practically always impaired in extensive pancreatic disease or dysfunction. But, after all, good health may be maintained on a high carbohydrate, high vitamin, normal protein, low fat diet.

There is clinical as well as experimental evidence that the pancreas is not absolutely essential. Functional pancreatic achylia with its butter stool, if treated with the proper diet, does not seriously affect the general health. Even in organic conditions where there is complete absence of this secretion, such as in a few cases of tropical sprue, a certain number of cases of cirrhosis and many cases of carcinoma of the head of the pancreas, death does not come early but at long last. Certainly in cases of carcinoma of the pancreatic head, the symptoms in the early stages—malaise, depression, pruritus, chills and fever, even pain—are not due to the cancer *per se* but are symptoms of a progressive jaundice with biliary toxemia. Thus the marvelous temporary improvement after cholecyst -gastrostomy or -duodenostomy! There is experimental evidence also in favor of this. For instance, in 1912, in a series of experiments made upon dogs with pancreatic fistulas, we found that as long as they were given plenty of fluids and plenty of alkali, their condition remained extremely good for a long period of time. If, on the other hand, the common biliary duct was subsequently ligated and a complete obstructive jaundice produced, in every case this was followed immediately by rapid loss in weight and strength and early death, emphasizing anew the great importance of the bile as a partial substitute for the pancreatic secretion if the latter is absent or markedly diminished.

These findings — clinical and experimental — are really of great significance for they justify partial or complete pancreatectomy for carcinoma. The salivary, gastric and intestinal secretion, and bile, possibly helped by pancreatin by mouth, will act as substitutes for the external secretion; insulin, possibly some day, pancreas transplantation, for the internal secretion.

Is pancreatic disease more common than is supposed or diagnosed? I am sure so. Can it be recognized or suspected more frequently than at present? I believe so, if one but keeps in mind its possibility in all cases with vague upper abdominal symptoms, with and without pain, and then utilizes all possible diagnostic procedures.

Perhaps there is no better way to end this fragmentary talk on the clinical aspects of pancreatic disease than to repeat what was said by Sir Archibold Garrod many years ago—"The chief difficulty in diagnosing disease of the pancreas is in thinking of the pancreas."

Surgical Aspects of Diseases of the Pancreas*

By

DANIEL F. JONES, M.D.
BOSTON, MASSACHUSETTS

IN a paper read before the New England Surgical Society in September, 1921, on "Acute Pancreatitis," I said that the term would probably always be used but that I would try to show that it was not descriptive enough and that the terms *acute pancreatic necrosis* or *acute hemorrhagic necrosis of the pancreas*, and *acute and chronic interstitial pancreatitis* would describe the various conditions found more accurately. I can find no reason for changing this opinion in spite of the fact that no one seems to have followed my suggestion.

Archibald (Lewis' "Practice of Surgery") has helped matters very much by dividing pancreatic cases into six groups, as follows:

(1) *Hyperacute pancreatic necrosis.*
(2) *Acute pancreatic necrosis.*
(3) *Subacute pancreatic necrosis.*
(4) *Acute pancreatic oedema.* (Zoepffel)
(5) *Chronic pancreatitis with recurrent subacute attacks.*
(6) *Chronic pancreatitis with sclerosis* (following acute attacks).

So far as dividing these cases into definite groups is concerned, this classification is of value, and if it were properly used we should not have such variation in the mortality statistics under the heading of acute pancreatitis as we have at present, when it varies from 22.7 per cent to 70 per cent or more. This great variation in mortality must be due to the variation in the type of cases used rather than to the difference in the skill of various surgeons.

My objection to this classification is that I believe there are two types of pancreatitis:

(1) Acute pancreatic necrosis, due to injury to the pancreatic ducts by retrojection of bile or duodenal contents into the pancreatic ducts, causing a digestion of the pancreatic parenchyma.

(2) An infiltration of the interstitial tissue with enlargement and an increased hardness and at times oedema. The condition may be either acute or chronic. The parenchyma of the gland is not involved. This should be known as interstitial pancreatitis.

With an idea in my own mind that the classification, etiology, pathology, symptomatology, and treatment of pancreatitis had been clarified to some extent, I was much disturbed to find that there was more confusion than ever about these points. It is impossible to discuss these cases until we can at least agree upon some classification, and classification cannot be agreed upon until the pathology has been agreed upon. Archibald has classified the cases of pancreatic necrosis, but what constitutes a pancreatitic necrosis? I have classified as pancreatic necrosis any case of pancreatitis in which there is fat necrosis or hemorrhage, because it is my belief that neither occurs without the release of activated pancreatic secretion which in turn causes pain and tenderness in the upper abdomen with nausea.

Archibald has a group which he calls chronic pancreatitis, which is due apparently either to very mild repeated attacks of pancreatic necrosis or to repeated attacks caused by the backing up of nearly normal bile into the pancreatic ducts, which he calls "subacute attacks of pancreatitis." He has still another group which he calls chronic pancreatitis with sclerosis, due to acute attacks of pancreatic necrosis, I assume, as only a necrosis could cause the amount of destruction he speaks of.

It has been my contention that there is an interstitial pancreatitis without involvement of the parenchyma, due to infection of the interstitial tissue. There are many cases of so-called interstitial pancreatitis of which there are no symptoms at any time, unless an abscess is formed and that seldom occurs. It is found only during the course of operation for other causes, such as cholelithiasis, peptic ulcer, or abdominal infection.

Three articles have been published recently in which various pathological changes have been classified under chronic pancreatitis and chronic interstitial or interlobular pancreatitis. Hinton (Annals of Surgery, September, 1932) states that duodenal and gastric ulcers in contact with the pancreas cause interlobular pancreatitis, which causes severe pain relieved at once by gastro-enterostomy. DeTarnowsky and Sarma (Annals of Surgery, June, 1935) describe *chronic pancreatitis* as a thickening of the gland due to repeated attacks of acute subsiding pancreatitis. Elman (Surgery, Gynecology, and Obstetrics, Nov., 1935) confuses the matter still more by reporting six cases of chronic *interlobular* pancreatitis, three of which had fat necrosis and three of which had no fat necrosis but had gall stones.

Under such conditions how is it possible to discuss chronic interstitial pancreatitis intelligently? I can only say that I myself have never seen a case of "chronic interstitial pancreatitis" without hemorrhage or fat necrosis diagnosticated before operation. Such conditions have no symptoms so far as I can determine.

The *mortality* of the two groups, acute pancreatic necrosis and chronic interstitial pancreatitis, is strikingly different. There is a mortality of at least 50 per cent in the cases in which the parenchyma is involved, while in the second group the mortality cannot be more than 2 to 3 per cent. If we accept Archibald's classification of acute pancreatic oedema (Zoepffel) as an acute interstitial pancreatitis, this would bring up the mortality rate somewhat. If, however, it is classed as acute pancreatic necrosis, as I believe it should be, the mortality rate corresponds accurately to the mortality rate of the acute pancreatic necrosis group.

*Delivered at the Thirty-ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936.
Approved by the Publications' Committee.

Not only are these two groups different in pathology, etiology, and mortality, but the two have entirely different symptoms. In the first group the patients are always operated upon because of symptoms due to the pancreatic necrosis or retrojection of nearly normal bile, while in the interstitial pancreatitis group they are operated upon because of symptoms due to biliary disease, duodenal or gastric ulcer (Hinton), or abdominal infections.

If we accept the division of these cases into the two groups, (1) acute and chronic pancreatitis due to activated pancreatic secretion or nearly normal bile, and (2) interstitial pancreatitis probably due to infection of the pancreas, and accept Archibald's division of the pancreatic necrosis cases into four groups, we can talk about the operative procedures and mortality of each.

There is some difference of opinion in regard to the type of operation to be performed. Archibald believes it necessary only to drain the biliary system. This appears logical, but what of the four autopsies reported by Opie some twenty-five years ago, in which the necrosis was limited to the area drained by the duct of Santorini which opened separately into the duodenum. While it is logical to drain the biliary system, there are undoubtedly a certain percentage of pancreatic necrosis cases due to retrojection of bile into the duct of Santorini. In fact, Opie states that the duct of Santorini is the main duct in 10 out of 100 autopsies.

The operative procedures for the various divisions of Archibald's classification should be settled in the minds of all surgeons. The extent of the operation should be determined by the condition of the patient. The very sick should have the least possible done; that is, drainage of the fatty capsule. If the surgeon believes it reasonable, a cholecystostomy with or without removal of stones may be done. Those in slightly better condition should have the fatty capsule and the true capsule, where soft areas are found, drained and a cholecystostomy done with removal of gall stones. In those patients in still better condition the gall bladder should be removed, the ducts explored, and a choledochostomy done.

It is self evident that drainage of the common duct will give freer flow than will drainage through the gall bladder, but it is necessary not infrequently to do a cholecystostomy because of the condition of the patient or because of the difficulty of reaching the duct.

Archibald does not approve of cholecystectomies for fear that the gall bladder may be needed for drainage later, but the great majority of surgeons do remove the gall bladder if the condition of the patient will permit it.

It is difficult to see the objection to drainage of the fatty capsule when it is infiltrated and tense and contains much broken down tissue. While I agree with Archibald in practically all of his work, I cannot agree that drainage of the biliary system is all that is necessary. I feel strongly that drainage of the fatty capsule, and the true capsule of the gland so far as it can be done without injury to the pancreas, is of great advantage to the patient. I have seen many patients relieved of pain and shock after drainage of the fatty capsule, and have had two very definite cases in which the patient remained uncomfortable, nauseated, and unable to eat after biliary drainage without drainage of the fatty capsule. Both were comparatively mild cases and both recovered after ten days which were very trying both to the patient and to the surgeon. I have never since neglected to drain the fatty capsule when there is swelling in the region of the pancreas, fat necrosis, or hemorrhage, no matter how slight.

It is true that drainage of the fatty capsule is more likely to cause an infection of the fat about the capsule than no drainage, but on the other hand proper drainage at the primary operation may prevent a secondary operation for the drainage of an abscess in this region. The neglect of early drainage of abscesses may, I believe, be responsible for some of the late deaths. When the fatty capsule is drained early, the patient frequently runs a moderate temperature or none at all for a week or ten days, at the end of which time the temperature rises to 101° or 103° with increased discharge of pus, broken down fat, and necrotic gland. A secondary operation is frequently necessary to give better drainage unless a large drainage wound is left at the first operation.

In addition to the difficulties of post operative drainage of the fatty capsule, these conditions not infrequently cause thrombosis of the veins in this region, not only the splenic vein but even the vena cava. The sepsis which is often present may cause infection in other regions, the same as any abdominal infection.

There have been changes in the minds of some surgeons recently in regard to the best time for operating on cases of acute pancreatic necrosis, largely because of the high mortality in these cases with our present method of so-called "early" operation. But are there enough cases operated upon within twenty-four hours to give us a proper idea as to the value of early operation? At the Massachusetts General Hospital early operation has largely been given up.

DeTakats and MacKenzie (Annals of Surgery, September, 1932) believe that:

(1) "Patients should never be operated upon in the initial shock," and yet their statistics show that the mortality in those cases operated upon within 24 hours is 25 per cent, the lowest mortality except for the group operated upon more than three weeks after the onset of symptoms. It may not be proper to operate within 2 to 6 hours after the onset, but it is a well known fact in surgery that removal of any condition causing shock will frequently save the life of the patient. The surgery must, of course, be reduced to a minimum. It is my belief, therefore, that all cases of pancreatic necrosis except the very mild should be operated upon at the earliest possible moment, first because of the possibility of an error in diagnosis, and secondly because I believe that there will be less destruction of tissue, and that the operation should be carried out under local anesthesia with a minimum of ether to keep the patient on the table during manipulation.

(2) "If all diagnostic measures point to pancreatic necrosis, delay is permissible until abscesses localize, cysts and gangrenous parts need removal." Yet their statistics show that operations delayed over 24 hours and up to 3 weeks have a mortality of 50 per cent. It is, I believe, important that all cases except the very mild ones be operated upon within 24 hours if it is possible to get the cases.

(3) "If diagnosis is uncertain, early operation must be done for fear of overlooking intestinal perfora-

tions." Operation within 24 hours would cover these cases.

(4) "If the attack is mild, wait for recovery and then diagnose and operate for biliary tract infection." Their statistics show that the mortality in cases operated upon more than 3 weeks after onset was only 20 per cent. It is quite evident that these cases were mild or operation would have been performed earlier. It would seem that the mortality of cases operated upon from 2 to 3 weeks after onset, 66 per cent, and the mortality of those operated upon after 3 weeks, 20 per cent, were unnecessarily high. It would seem reasonable to expect a lower mortality if all operations had been done within 24 hours.

May I diverge for a moment to mention *diagnosis* and to say that laboratory examinations, at least those in use up to the present time, should not make one give up physical examination, for every available method should be used in the diagnosis of these difficult cases. The most satisfactory aid to making such a diagnosis is the careful determination of the location of tenderness. It is not enough to say that there is tenderness in the upper abdomen. Given symptoms suggesting gall bladder disease, the diagnosis of pancreatitis should be made correctly in a high percentage of cases if there is tenderness extending to the left from the gall bladder. This can be accomplished only by meticulous care as to the amount and extent of the tenderness. Experience is necessary, of course, to make this distinction and yet a former resident, of very moderate hospital experience, made a correct diagnosis in the next two cases that were admitted after he had been taught this method of diagnosis.

I appreciate that there has been much written recently about attacks of pancreatitis causing pain, indigestion, and discomfort in the upper abdomen after cholecystectomies and cholecystostomies, but I have not seen enough of these cases to make me feel that pancreatitis following cholecystectomy and choledochostomy is of much importance. It is true that at operation I have left stones which have had to be removed at a second operation, but this has always given relief. I have operated twice for attacks of pain following operations for gall stones without finding any cause for the pain, even pancreatitis, but in spite of this there was no further occurrence of the pain after several years.

It is quite evident from various case reports that there is frequently more than one attack suggestive of pancreatitis before operation seems necessary. In 1921 I called attention to the fact that 22 of the forty-three cases of acute pancreatitis from the Massachusetts General Hospital occurred in patients without gall stones, and of these 17 had had one or more attacks of pain before having an acute attack of pancreatic necrosis requiring operation.

Archibald believes the mild attacks to be acute pancreatitis due to retrojection of nearly normal bile into the pancreatic duct, which causes an inflammation and therefore swelling, but not a necrosis. Whipple and Goodpasture (Surgery, Gynecology and Obstetrics, 1913, XVII, 591) report that in animals there may be attacks of pancreatic necrosis with absorption of the necrotic material which leave a scar so small that it is difficult to find it. How such a condition can produce the findings of deTakats and MacKenzie is difficult to understand.

"Indigestion" and slight discomfort in the epigastrium do not have much significance for me. When we consider the various operations which have been carried out for the relief of these symptoms, we wonder if these symptoms really mean much. The outstanding reasons given for such symptoms before operation have been chronic appendicitis, chronic salpingitis, retroversion of the uterus, so-called chronic cholecystitis without stones together with an X-ray showing a gall bladder which does not empty quite as the roentgenologist thinks it should, stasis in the duodenum, duodenal diverticulum, and now chronic pancreatitis either before or after operation. One is not much impressed with the value of these symptoms when they are supposed to be "cured" but such different operations. In many clinics chronic cholecystitis without stones makes up at least 50 per cent of all the gall bladder operations. One wonders why we do not all have our gall bladders out for slight indigestion and perhaps a fulness in the upper abdomen. It has been said by some surgeons that cases of chronic choecystitis without gall stones should be operated upon not only for relief of "indigestion," but also for fear they may cause pancreatitis! In spite of this great danger, Wilkie has said that he has had great difficulty in finding a bacteriologist who could find bacteria in the gall bladder walls for him, and yet he considers operation of great importance. If these symptoms are of value, why has it been necessary to do so many different operations for the relief of them, and why are patients not more often relieved by the operations?

Operations for the relief of acute interstitial pancreatitis do not seem to be necessary as the symptoms do not seem to be sufficient to make a diagnosis possible, or at least to make an operation necessary, as such a condition is rarely if ever seen at operation unless we consider Zoepffel's acute oedema of the pancreas as an acute interstitial pancreatitis.

The treatment of chronic interstitial pancreatitis is incidental to finding it in the course of operations for other conditions such as cholelithiasis, duodenal or gastric ulcer, acute cholecystitis, or some abdominal infection, and should consist, I believe, of the removal of whatever is the cause of the pain. To make doubly sure, it is important to drain the biliary system especially if there is jaundice. Many cases of chronic pancreatitis have been relieved entirely by cholecystectomy alone, without drainage of the biliary system. Long continued drainage of the biliary system has been emphasized by many surgeons, especially Deaver, but drainage for two weeks is sufficient in all the cases I have seen. Deaver recommended and carried out on several patients cholecyst-gastrostomy in cases in which jaundice had recurred or had not cleared. It has been my good fortune in about 2500 cases of cholelithiasis and cholecystitis never to have been obliged to do a cholecyst-gastrostomy for chronic interstitial pancreatitis. It seems probable that when any such operation is necessary, the condition present may be carcinoma of the head of the pancreas.

As to *preventive measures* in pancreatic disease, there is no doubt but that removal of gall stones when found is an excellent measure, but I cannot agree with those who feel that it is important to remove the gall bladder in cases of so-called chronic cholecystitis without stones, to prevent acute or chronic pancreatitis. The arithmetic of these men seems to me to be at

fault, for in my own practice I have operated upon forty cases of acute pancreatic necrosis and abscesses of the pancreas, while during the same period I have seen more than 2500 cases of cholelithiasis. That is, about 1.6 per cent of all the cases of cholelithiasis and acute cholecystitis are associated with acute pancreatic necrosis.

As the mortality of acute pancreatic necrosis is about 50 per cent, the mortality rate for these acute pancreatic necrosis cases associated with cholelithiasis and acute cholecystitis could not be more than 0.8 per cent. The operative mortality for cholecystectomy in cases of chronic cholecystitis could not be less than 2 per cent, which leaves a balance of 1.2 per cent in favor of not operating upon these cases.

While it must be admitted that there is little that is new in regard to the *treatment* of pancreatitis, we have a most brilliant piece of clinical work on carcinoma of the pancreas, for which we owe a debt of gratitude to *Drs. Whipple, Parsons, and Mullins, regardless of* whether the late results will or will not be commensurate with the brilliancy of the clinical deductions that have been made.

It must have been appreciated by every surgeon that pancreatic secretion could not get into the duodenum in cases of carcinoma of the head of the pancreas with marked jaundice, yet no one has ever before drawn the conclusion that the pancreatic duct might be tied off without doing any damage to the individual. This clinical observation has brought many cases of carcinoma of the pancreas into the field of operative surgery. Not only is the observation and proof that the patient can exist without the external secretion of the pancreas of importance, but the carefully worked out operative procedure is of great importance. (Whipple, Annals of Surgery, October, 1935).

It has taken many years to convince surgeons that the pancreas can be operated upon the same as any other organ, provided one is careful to prevent leakage and infection. In fact, it has been found that the pancreas can be incised or large sections removed without danger to the patient. To have this proof that patients can live with the pancreatic duct tied off gives the surgeon control over the whole pancreas. A large part of the tail can be removed from the tail toward the head without doing harm, and now that Whipple, Parsons, and Mullins have proved that the pancreas can be partly removed from the head toward the tail, the whole organ is under control.

Not only is this work of importance in carcinoma, but it will make the removal of cysts much more certain than formerly. Removal of a portion of the pancreas with the cyst may be done with the hope of no further trouble, for few have attempted to remove cysts of the pancreas with any feeling of certainty that they would not recur. With our present knowledge of the pancreas, removal of sufficient gland tissue to make sure that a cystadenoma or a simple cyst will not recur is of importance. Degeneration cysts or pseudocysts should not recur, and simple drainage is all that is necessary.

Probably the most spectular operations on the pancreas are those for hypoglycaemia due to adenomata or to hyperplasia of the pancreas. In addition to the adenomata, which give such striking results when removed, there is apparently a hyperplasia similar to hyperplasia of the thyroid gland. Some cases have been operated upon in which no adenoma can be found. In order to treat these cases, an unexpectedly large proportion of the gland must be removed, as in thyroidectomy, in order to reduce the insulin sufficiently to return the patient to normal. Unfortunately the problem is more difficult than in thyroid disease because of the greater risk in opening the abdomen two or more times to reduce the gland sufficiently.

In all operations for removal of a large or small part of the pancreas the great danger is in injury to the blood vessels in the region of the pancreas. Removal of the spleen may be necessary because of injury to the blood supply or to facilitate the removal of a growth.

The operation for hypoglycaemia and Whipple's operation for carcinoma of the pancreas have been the outstanding clinical advances in surgery of the pancreas in many years. Let us hope that within the next ten years the etiology, classification, diagnosis and treatment of pancreatitis can be put on a more definite basis than it is at the present time.

Thoracic Stomach with Short Esophagus and Diaphragmatic Hernia*

By

LEON BLOCH, M.D., A. M. SERBY, M.D.

and

SAMUEL SALINGER, M.D.

CHICAGO, ILLINOIS

"DIAPHRAGMATIC hernia" was the all inclusive term applied to a protrusion of the stomach through the diaphragm, until Bailey (1) introduced the name "thoracic stomach" to that type due to a shortening of the esophagus. There is a tendency to ascribe all of these lesions to a congenital, actual or potential defect in the diaphragm in contradistinction to the traumatic form of hernia through the diaphragm. A potential widening of the hiatus esophageus may, however, be a predisposing factor in the causation of the latter. In three patients of our series, an hiatus large enough to admit three fingers was found at the time that an operation was being performed for some other condition. Where formerly

*Delivered at the Thirty-ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936. Approved by the Publications' Committee.

Fig. 1

diaphragamatic hernia was considered to be the more frequent lesion, it seems that the diagnosis of hiatus hernia and congenitally short esophagus is gaining in ascendency. An adherence to Akerlund's (2) classification of three types would help to clarify the situation immeasurably. There will be however, because of a lack of diagnostic methods, a large number of cases which will be unclassifiable.

Our interest in this subject was aroused by the fact that we were encountering these lesions in greater numbers, undoubtedly due to an increasing number of reports in the literature, and an increasing ability to recognize them. Therefore, when we decided to study this condition more thoroughly, we recalled as many of our patients as we could, in whom the diagnosis of "diaphragmatic hernia" had been made previously, with the purpose of trying to differentiate them into recognizable types. As we were only partially successful in our attempt, one of us enlisted the aid of esophagoscopy and later biopsic examination as suggested by Clerf and Manges (3). It is quite obvious that this kind of examination is superior to that of localizing the length of the esophagus by the level of the thoracic vertebra, although the latter is a much simpler procedure. Unfortunately we were unable to obtain the consent of all the previously examined patients to return for another fluoroscopy and still less for esophagoscopy. While we were thus enabled to increase our ability to differentiate the types, we did not acquire a corresponding increase in our facility to make a clinical diagnosis of the condition beforehand. On several occasions we suspected the lesion, only to find ourselves wrong in the majority of cases. We are inclined to agree with Ritvo (4) that in the majority of the cases it is an accidental finding without characteristic symptoms. The symptoms related by the patients are more frequently due to some other underlying cause. If more individuals were examined roentgenologically, the lesion would undoubtedly be found more frequently.

Incidence: Eleven patients were males and twenty-seven females. All of our cases were in adults. The ages ranged from 31 to 70. Only seven of these were in the seventh decade of life.

Symptoms: A restatement of the symptoms will be nothing new. We shall therefore make an analysis of the symptoms encountered in the hope of finding out which ones, singly or in combination, might suggest a diagnosis before other methods of investigation are utilized.

Twelve complained of epigastric pain, for periods varying from one to twenty-four years. In three of these the pain was worse at night, or on lying down, and in four it radiated to the left. One patient stated that the pain was distinctly worse on attempting to lift a heavy weight, Fig. 1. This patient, a woman of 51, was seen in 1933 because of pain in the right upper quadrant of the abdomen of eight years duration. She had some pyrosis which was relieved by soda bicarbonate, but no dysphagia. The gall bladder concentrated the dye normally. We mention this negative point because on X-ray examination a narrowing of the esophagus was found in addition to a large supradiaphragmatic gastric pouch. She came to the hospital for esophagoscopy and then changed her mind. This is probably a case of thoracic stomach on the basis of a congenitally short esophagus.

In the four patients whose pain radiated to the back, the lesion was of medium size in two, large in the second, and small in the third. In the last patient the esophagosopic length was 40 cm. and biopsic examination revealed esophageal tissue at that distance. The impression obtained, therefore, is that this might well be a case of para esophageal diaphragmatic hernia, which incidentally is the impression obtained on fluoroscopic examination. Another patient, female, age 51, with a medium sized gastric pouch had complained of severe pain in the left upper quadrant radiating to the back for many years—in fact as long as she could remember. The pain came on immediately after meals and was made worse by a heavy meal. Occasionally

Fig. 2

the pain occurred at night. The gall bladder concentrated the dye normally. The esophagoscopic length was 40 cm.

The mucosa at the cardiac orifice was reddened. Biopsic examination revealed gastric tissue. This is probably another case of para esophageal hernia. Three of these twelve patients had cholelithiasis.

"Heartburn" occurred in twenty-two patients, in seven of whom it was relieved by soda bicarbonate. In eight, it was definitely worse at night or occurred only on lying down, to be relieved when the patient assumed an upright position. In three of these the lesions were of medium size and associated with esophageal constriction above the gastric pouch in two. In one of these, a patient, age 56, who was afraid to lie down because of heartburn, esophagoscopy revealed an hyperemic mucosa which bled easily, and a thickening of the posterior folds at a level of 32 centimeters. In spite of this definite picture of esophagitis, her only complaint was nocturnal pyrosis without dysphagia. Another patient, a male, age 11, complained of heartburn for about eighteen years, when lying down. X-ray examination revealed a large gastric pouch with an esophageal constriction. The esophageal length was 37 centimeters. The diagnosis is probably thoracic stomach with short esophagus.

Six of these twenty patients had cholelithiasis. How much the pyrosis was due to this and how much to the gastric lesion, is difficult to tell. In the majority of cases there was no relationship between the size of the lesion and the amount of heartburn.

Vomiting, alone or with regurgitation, occurred in ten patients, and regurgitation in four. Relief of the distress by vomiting was not common. In five of these patients the lesion was small, in two large and one medium.

Pain in the chest, either of a substernal type or radiating to right or left, occurred in only 6 patients. One of these patients came to see us in 1931 complaining of irregular gastro-intestinal discomfort. Two years before, a diagnosis of chronic cholecystitis was made in Detroit by very capable physicians. At times the patient complained of severe right hypochondriac pain. About one year later he had severe pain in the left precordial region, radiating to the left shoulder and arm. The gall bladder concentrated the dye well and an electrocardiogram showed no deviations from normal. A tentative diagnosis of diaphragmatic hernia was recorded on the history, but it could not be confirmed by X-ray examination. Four years later the diagnosis of thoracic stomach and short esophagus was made at the Mt. Sinai Hospital, New York, while the patient was under the care of Dr. Winkelstein. Hurst (5) reported the case of a patient with recurrent hernia of the stomach through the hiatus esophageus of the diaphragm with pain resembling angina pectoris. Three patients in this group had dysphagia, but esophagoscopy was unsuccessful in two and not tried in one. One other patient in this group will be discussed later. In two it was undecided whether the pain was referred into the chest from calculous cholecystitis, or from the gastric pouch.

A history of dyspnea was obtained in six patients. In all of these the lesion was either of medium or large size. Goodall and Hoyt (6) lay great stress on dyspnea of a peculiar type which occurred in four of their five patients. They found a characteristic dyspnea, one occurring on the slightest effort or after eating—a sort

Fig. 3

of panting breathing—disappearing when the patient sits down and prone to be absent even on exertion, when the stomach is empty.

They divide their cases in two types—one in which the major part of the stomach is above the diaphragm, and the other in which the major part is below the diaphragm. The intense type of this remarkable form of dyspnea occurs in the first type and lead the authors to make a clinical diagnosis of thoracic stomach in two other patients, after having found a thoracic stomach on X-ray examination in the first patient who had this sort of breathing. We did not encounter this severe symptom in any of our patients because the lesions were all of the second type, with the exception of one who refused to come back for a re-examination. Six patients complained of some form of dyspnea. One in this series, Fig. 2, a woman of 38, complained of epigastric pain, nausea, vomiting, tightness and a smothering sensation of the chest with frequent attacks of dyspnea. She had stomach trouble dating back to childhood. In 1926 she was told that she had asthma. An X-ray examination revealed the largest thoracic stomach in our series. Unfortunately we lost track of her and could not get her back for re-examination or esophagoscopy. In the light of Goodall and Hoyt's report and the fact that her symptoms dated back to childhood, we are inclined to consider this case as one of congenitally short esophagus and thoracic stomach.

Dysphagia occurred in six patients. In the report of Clerf and Manges (2) dysphagia was a prominent symptom. Their patients differed from ours in that the majority came to them primarily for difficulty in swallowing. The lesions were of medium size in two, small in three, and undetermined in one. Two had indefinite chest pain and three heartburn at epigastric

pain. Esophagoscopy was carried out unsuccessfully in three patients.

They refused to return for re-examination. X-ray examination revealed a supragastric constriction. One of the patients ,Fig. 3, male, age 62, had difficulty in swallowing over a period of two years and had had repeated attacks of biliary colic. X-ray examination revealed a thoracic stomach with an esophageal narrowing and cholelithiasis. A cholecystectomy was done, at which time it was found that the hiatus esophageus admitted three fingers quite readily. The dysphagia returned later. Esophageal dilatation gave him some relief. Esophagoscopy was attempted, but because he violated instructions not to partake of fluid and denied having done so, it was unsuccessful as gastric fluid regurgitated into the esophagus at the time of examination. He refused to return for re-examination.

In attempting to *evaluate these symptoms*, we were confronted by the fact that many of the patients who had other pathological conditions, as calculous cholecystitis (11 cases), hypertension with or without cardiac involvement (8 cases), hyperthyroidism (2 cases) and syphilis (2 cases), had the same complaints as those patients with thoracic stomach without these lesions. It is, therefore, very difficult to determine upon a symptom complex which is typical of thoracic stomach. The following symptoms are suggestive: increased pain or heartburn on lying down, pain in the chest radiating to the left or down the left arm and dyspnea, neither one of cardiac origin, and difficulty in swallowing of long duration in a patient in whom traumatic stricture, carcinoma of the esophagus or cardiospasm can be ruled out.

X-ray examination: In every case the actual diagnosis was made by X-ray examination. Attempts to visualize both the hernial protrusion and the esophagus as suggested by Einhorn (7) were unsuccessful in most cases. It was necessary to give the patient some more barium and visualize both structures at the moment of the passing of the barium. This should be an excellent method for differentiation. Unfortunately a second meal of a thick paste was not always successful. We classified our lesions as small, about 3 centimeters or less in diameter, medium 4 to 6 centimeters, and large 7 centimeters or more. Fifteen were small, eleven medium and eight large.

X-ray examination alone sufficed to make a diagnosis of para esophageal hernia in seven patients, in one of whom it was confirmed by a double meal, and in six by finding the esophagus to be of normal length. In one patient dilatation of the esophagus by X-ray was found and esophagoscopy revealed shortening. In six patients the finding by X-ray of a constriction of the lower end of the esophagus with a supradiaphragmatic gastric pouch suggested the presence of a short esophagus. Only one of these was confirmed by esophagoscopy alone, as the other patients refused to return for further examination.

Esophagoscopy was employed for the purpose of getting information about the condition of the esophagus, determining its length and later to obtain specimens of tissue at the level at which gastric mucosa was seen. It is ordinarily accepted that the distance from the teeth to esophagus is 40 centimeters. However, this may vary some with the heighth of the patient. In this report 39 to 40 centimeters are accepted as normal, except in those patients in whom a constriction is found at the lower end of the esophagus, in addition to roentgenological evidence of a supradiaphragmatic pouch of the stomach. Because of our inability to have all patients with this possibility return for esophagoscopy, we are unable to furnish any definite statistics on this point. Esophagoscopy was carried out in fifteen patients. In nine it was responsible for the diagnosis, and in six it confirmed the diagnosis made by X-ray.

The results of *biopsic study* in nine patients showed that gastric mucosa was obtained in three patients at a level where the esophagus should be, and esophageal mucosa in the others. Because of a constriction at the lower end of the esophagus in three cases, it was impossible to enter the stomach. X-ray examination, however, revealed the fact that the esophagus was constricted above a small protrusion of the stomach above the diaphragm. In some patients in whom the esophagoscope was passed to the 39 or 40 centimeter mark, there is still the possibility of the lesion being a paraesophageal hernia—that is, a real diaphragmatic hernia. Many more studies will be necessary to determine this fact. In all cases where a biopsy was made, the esophagoscopic diagnosis was confirmed. It seems unlikely that this method of examination is necessary except in extremely doubtful cases.

SUMMARY AND CONCLUSIONS

1. Thirty-nine patients were seen with the diagnosis of some type of thoracic stomach. In 7 the lesion was a paraesophageal hernia. This diagnosis was confirmed by X-ray examination and finding the esophagus to be of normal length. In one it was confirmed at fluoroscopy by a double meal. Many may question the frequency of this lesion, and rightly so, because of the tendency to consider most of them to be due to congenital shortening of the esophagus.

2. In nineteen the diagnosis was thoracic stomach due to a shortened esophagus. In six a constriction of the esophagus above the gastric pouch was seen. In 9 the diagnosis of short esophagus was made or confirmed by esophagoscopy. In one the history of difficulty in swallowing and finding a constricted esophagus by fluoroscopy, and in another the history of gastric disturbance from childhood on, without an esophageal constriction, were sufficient to make the diagnosis. In one patient the diagnosis was made elsewhere. In 12 it was impossible to determine the kind of lesion found.

3. A clinical diagnosis of thoracic stomach should be suspected in patients presenting the above mentioned symptoms over a long period of time, in whom other pathological conditions can be ruled out.

4. The thoracic stomach of unknown type requires more careful examination by various methods, as X-ray, double meal and esophagoscopy for differentiation.

5. Biopsy is only a confirmatory procedure and is unnecessary where esophagoscopy is satisfactory.

DISCUSSION

DR. JOHN H. FITZGIBBON (Portland, Oregon): Dr. Bloch did not mention bleeding as a complication of diaphragmatic hernia. I have seen over thirty cases, out of which group two patients have had severe hemorrhages and a history suggestive of peptic ulcer, but with no X-ray evidence of abnormality other than hiatal hernia. It is reasonable to assume that they were bleeding from ulceration in the herniated part of the stomach. Both responded well to ulcer management and are continuing treatment. The recurrence of ulceration without hemorrhage in these patients is something that should be given serious consideration. If stools are routinely examined, we shall find occult blood continuing over long periods in many. Secondary anemia is occasionally an outstanding feature.

Dr. Bloch's paper brings out the fact that hiatal hernia is rather common, and I feel that we should emphasize the importance of horizontal fluoroscopy. No gastro-intestinal X-ray examination is complete unless the patient is examined lying flat or with the head lowered. Upon taking a deep breath and straining, barium will be seen to "pop" up through the hiatus into the hernia. If this sort of examination is made routinely, particularly in people who have been suspected of having gall bladder disease or who have been operated upon for supposed gall bladder symptoms without subsequent relief, hiatal hernia will be found much more commonly than is generally realized.

DR. RALPH C. BROWN (Chicago, Illinois): Adding to what Dr. Fitzgibbon has said, I am convinced that peptic ulcer occurs in association with these hiatus herniae, possibly resulting from the ischaemia produced in the mucosa of the stomach at the point of constriction. I have seen massive hemorrhage in association with at least one such case, and in two other cases there was such a degree of perigastritis at the point of constriction of the stomach as to involve the esophagus in scar-tissue to such a degree as to produce obstruction which required dilatation.

I think the probable association of peptic ulcer with hiatus hernia is something which at least should be kept definitely in mind. It is difficult to see the ulcer lesion when it exists at the point of constriction, so I am not able to state with absolute certainty that peptic ulcer occurred in the three cases to which I have referred. However, all three of these cases responded immediately and permanently to the therapeutic test of routine ulcer management.

DR. JOHN L. KANTOR (New York City): In addition to frank hemorrhage, there may be oozing in cases of diaphragmatic hernia. This is one of the causes of obscure anemia that should be kept in mind.

There was one case of this kind in New York that masqueraded as carcinoma. It was discovered by the late Dr. Rothschild, an internist. It is well worth knowing that by examining these people in the ordinary erect position and giving them a Sedlitz powder, one may bring out a second shadow parallelling the diaphragm but higher up in the chest. This shadow represents the gas filled intra-thoracic portion of the stomach. The procedure was devised by Dr. Ball and published in the *J. A. M. A.*, October 19, 1935.

DR. LEON BLOCH (closing the discussion): None of these patients had an apparent hemorrhage, but one had a definite ulcer which we could see with the esophagoscope very distinctly and bleeding had occurred. In all of the patients in whom esophagitis was found by the esophagoscope there was no question about the diagnosis: the mucosa was red, hyperemic, spongy and bled very readily so that undoubtedly had we examined the stool we might have found blood.

In two of the patients we found not only esophagitis but gastritis extending below the esophageal gastric margin.

The method of examination, of course, is important. All of the patients were examined, either lying down or in the Trendelenburg position. In most cases it is a simple matter to examine the patient in either the right or left oblique, or in the supine position. There was no difficulty in finding the lesion. Once in awhile we were aided in finding the lesion by having the patient take a deep breath, because when the diaphragm descended the gastric pouch came up very distinctly.

Specific Food Sensitiveness*

By

WALTER C. ALVAREZ, M.D.†

ROCHESTER, MINNESOTA

IN the time available I can report only briefly on some of the impressions that stand out strongly from the experience of the last few years. First, I would like to say that there is no question in my mind about the need for the development of a greater interest in specific food sensitiveness on the part of gastro-enterologists and, for that matter, of physicians practising in every field of medicine. We should all of us be grateful to the allergists for having opened our eyes to the possibility of relieving several distressing syndromes, such as migraine and mucous colitis, by the forbidding of certain foods.

Dietitians also could profit from conversion to the view that the *digestibility* of a food may at times be much more important to a patient than is its content of vitamins or calcium or iron. So far, most of the books on dietetics either ignore the subject of digestibility or else dismiss it with a few words, and the individual dietitian, unless she has been specially trained under an allergist, is likely to have little patience with anyone who claims that he cannot take milk or eggs or spinach or orange juice. Time and again highly allergic patients have told me of the miserable experiences they have had in hospitals where, after an operation, they were forced to continue eating the so-called "health foods" long after the prophesied vomiting or painful bloating appeared.

Perhaps I should say that the outset that I have no intention of joining the group of enthusiasts who seem to believe that nearly every disease is due to food allergy. Perhaps when I have learned more about this subject my percentage of miracles and cures will be higher, but as yet I must admit that I meet with far

*Delivered at the Thirty-ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936.

†Division of Medicine, The Mayo Clinic.

Approved by the Publications' Committee.

more failures and disappointments than with successes. In many cases I haven't even the desire to start experimenting with diet because the history suggests so strongly that the troubles are not due to the nature of the food eaten. This is particularly true when short spells of discomfort alternate with intervals of weeks or months when the patient is able to digest anything. In such circumstances, if the inciting factor were a food it would have to be one seldom eaten, and in such circumstances the patient would probably have recognized his idiosyncrasy. Or a woman with migraine will tell me that her headache comes only with menstruation or when she overworks or sits up late waiting to scold a wayward son, or when she takes a long automobile ride.

To be sure, in some of these cases migraine or vasomotor rhinitis may come as the result of the combined action of two insults, and the removal of wheat or some other food from the diet may enable the brain or the nose to withstand the effects of fatigue or menstruation or dust. Especially when, in a given case, facts in the history have warned the physician that the symptoms are probably not due to food, he will feel disinclined to keep on experimenting with narrow elimination diets unless they soon show definite signs of bringing relief.

Although, as I have said, I meet with more disappointments than miracles, when the miracles come they are so delightful that I feel that we physicians all owe it to our patients, to our reputations and to the good name of scientific medicine to keep constantly on the watch for cases in which remarkable successes can be attained.

Perhaps it would help if I were to stop for a moment to recount briefly three or four of the experiences which have convinced me that even those of us who are much interested in food sensitiveness must still be failing to recognize cases of the disease and must be turning away patients whom we could easily cure.

Thus, a few months ago, I saw with Doctor Rozendaal a young man who said that he was well until about seven years before, when he was a sophomore in college. He then began to have so much flatulence, abdominal pain, and mental cloudiness that study became almost impossible and he had to go home. There, in spite of treatment by many physicians, he continued to suffer so much that he could seldom do any work. My impression from looking at the man and listening to his story was that his mental deterioration was his part of a poor nervous inheritance which had produced a syndrome suggesting mild epilepsy in a brother, and I had no hope of helping him. All laboratory and roentgenologic reports were negative. It was only a forlorn hope that led us to experiment to see if an elimination diet would affect the abdominal distress. To our astonishment, he returned in forty-eight hours a different person. For years dull, apathetic and discouraged, he now was bright and wide awake, his ambition had returned, his head had become clear, his abdominal discomfort had disappeared, and he had begun to eat and to gain in weight. Soon he was able to work all day on his father's farm, and after a few months he wrote to say that his health was good so long as he avoided certain foods.

A physician was seen for several years with severe hunger pain, so typical of ulcer that it never occurred to me or to any of my colleagues to suggest a study of food sensitiveness. At times the pain was so severe that milk had to be taken every hour. Eventually the abdomen was explored, an ulcer could not be found, and pyloroplasty failed to give relief. In February, 1935, after an attack of asthma, skin tests were made and a tremendous sensitiveness to milk was discovered. Removal of this food from the diet brought immediate relief, and later it was found that orange juice and chocolate also had to be avoided. Since these three offending foods have been excluded from the diet, the patient has been perfectly well. I have seen now several such cases in which a desperate effort was being made to cure hunger pain with the very thing which was causing it; namely, milk!

For several years a man kept coming to The Mayo Clinic complaining of a sort of narcolepsy severe enough to cause him to fall asleep at the wheel of his car or while talking business in his office. All attempts at treatment had failed. Last year, when careful questioning revealed the fact that most of his trouble followed breakfast, I suggested that he go without this meal and then, if that helped, he could test one food at a time until an offender was found. I had little hope that he would find a cure this way and I had forgotten all about the man when, some months later, his home physician wrote that the avoidance of cream had worked a complete cure.

This brings me to another point that still deserves much emphasis, which is that *hurtful foods so often injure or irritate the brain.* To my surprise, once, while trying to cure hives in a man who had not worked for years on account of distressing feelings in his head, I accidentally cured the "insanity" and the man went back to take charge of his business again. On another occasion I saw a man in *status epilepticus* which was due apparently to his having gorged himself on strawberries, and I have seen people who knew that they would develop a vile temper if they ate certain foods. We all know that nightmares can follow the eating of a "Welsh rabbit," we know that splitting headache or migraine can follow the eating of chocolate or cheese, and I happen to know from personal experience that the eating of chicken or eggs can give rise to weird visions, annoying dopiness and even signs of meningeal irritation.

Besides the few cases in which a cure comes as a welcome surprise, there are, of course, the many in which it is to be expected because the patient has already learned that one or more foods will produce the symptoms complained of; he continues to suffer only because neither he nor his physician knows how to go about the business of discovering all of the noxious agents. If he is intelligent, all he needs to start him on the road to recovery is a little instruction in home detective work.

Obviously we cannot afford to waste time hunting for food sensitiveness in every patient, so the next question is: in what type of case should we be particularly careful to look for it? My impression now is that *we should look carefully for food sensitiveness* whenever the symptoms of abdominal distress point to the presence of an overly-sensitive colon, or when they are vague or unusual, or whenever careful examination fails to reveal any sign of disease in duodenum, stomach, gall bladder or appendix. We must study the diet in every case of true flatulence or bloating, and

we must look for food sensitiveness in some cases of migraine.

I doubt if it pays to study diet in every case of *migraine* because so often the history tells us that we are not likely to get anywhere along these lines. The headache may come only when the woman is menstruating or when she is very tired or has had an emotional debauch; or we may see at a glance that we are dealing with a psychopathic or markedly asthenic person or one whose brain has been made so irritable by overwork, worry, grief or pain that the little "explosion" that causes the attack can take place every few days without the help of any extra insult, such as can be derived from food. This type of case is so common that I doubt if any large percentage of people with migraine can be relieved by dieting alone.

Occasionally I can help a person with vasomotor rhinitis, but there are many more whom I do not help, again apparently because the sympathetic nervous system is so irritable and erratic that it can cause trouble without the help of irritants coming from without the body. Similarly I have had almost no luck in helping patients with the severe and almost constant type of urticaria. Often it seems to be brought out by worry and mental strain. I have had some luck in treating canker sores in the mouth; in one case, after a life-time of suffering, relief came when chocolate was removed from the diet. As I have already pointed out, we physicians must always be on the watch for patients whose feelings of autointoxication may perhaps be cured by dieting. It sems probable also that in some cases constipation is due to the irritation of the colon by certain foods, and in some, the symptoms of cholecystitis, ulcer or appendicitis can be imitated with great fidelity.

I should like to emphasize the point that it does not seem logical to assume that most of the annoyances that follow the eating of particular foods are allergic in origin and due to protein. I feel sure that there must be a number of drug-like substances in certain foods which can upset the digestive tract in much the same way as it might be upset if a person were to take a small dose of an emetic or a purgative. Instead of frank vomiting, there is regurgitation, belching, heartburn, and discomfort about the cardia, and instead of purgation there is peristaltic unrest and colicky pain.

Whether or not one accepts the view that food sensitiveness is usually due to the protein in the food, I cannot see why one should make strenuous efforts to purify the allergens used for skin testing. I should expect to get the best results with antigens obtained by the simplest treatment of the foods.

Another point that I would like to stress is that it is neither logical nor necessary to keep a patient on a narrow elimination diet for weeks or months as some physicians are doing at the present time. It seems to me that if good results are not secured in two or three days, one of two things is probable: either the diet still contains an offending substance or else the cause of the symptoms is not to be found in food. Rarely have I seen any good come from the continued use of an elimination diet that did not bring relief in forty-eight hours. This is to be expected from the fact that when a person eats some harmful food the symptoms generally appear within a few hours. Accordingly, when a patient returns after having been for forty-eight hours on a narrow elimination diet and says that he is no better, the physician must not ask him to keep on for a month but must face the situation immediately. He must either accept defeat and tell the patient to return to his usual habits of eating, or else he must continue experimenting with substitutes in the elimination diet. If this does not help the patient can fast for a few days.

Ordinarily I start patients on a diet of lamb, rice, butter, sugar, and canned pears. If after a few days their distress persists, I may leave them for two days on nothing but maple sugar, or I may ask them to fast. If after this they still have their distress, I lose faith in my ability to help them with diet. Rowe tells me that sometimes in cases of wheat sensitiveness it takes ten days or a month to get the offending protein out of the system, but if it took me that long to help a patient with diet, I would suspect that the relief that came was due to some other factor such as rest, unconscious psychotherapy, or a spontaneous remission of symptoms.

Even when the elimination diet fails to help, it often gives much valuable and even decisive information as to the nature of the patient's troubles. Particularly in the case of women, one can learn so much from the way in which an individual faces or fails to face the little annoyances associated with the dieting. Often she frets so much, she acts so unreasonably, and she shows herself so irritable and so lacking in backbone and good sense that the diagnosis of "Fox's disease" can promptly be made. For those who are not acquired with Fox's disease I will say that, one morning, a chief asked his interne, named Fox, what he thought was the matter with a certain woman whose case he had just been working up. The answer was, "Well, doctor, it looks to me as if she were just a plain damn fool!" The chief was so entirely satisfied with this diagnosis that thereafter, in that hospital, the particular syndrome was known as Fox's disease.

Another point that has been impressed on me time and again in the last few years is that commonly the skin tests not only fail to help the physician in his search for offending foods, but sometimes the obtaining of a few positive results is actually a nuisance because both the patient and his physicians put such a blind and unswerving faith in them. In many cases it is almost impossible to get the patient to touch the incriminated foods again. I have spent hours trying to get these people to see that the reaction of the skin may or may not have supplied a trustworthy hint. In every case one should proceed with the experiment of eating the suspected food to see if this makes the symptoms any worse, or of avoiding the food to see if this brings relief. Surely no food should be banned forever simply because the skin once reacted to it. Sometimes when the tests are repeated the skin is found to respond to a different set of foods.

The difficulty is that we human beings are all a bit lazy; we dislike thinking and reasoning, and hence whenever possible we cling to a laboratory diagnosis which we hope will save us from having to work one out for ourselves.

SUMMARY AND CONCLUSIONS

To sum up, then, although there are more disappointments than miracles in the search for and the curing of severe manifestations of food sensitiveness, the miracles are so gratifying when they come that, each time, the clinician will resolve to spend more time looking for them. The field is still much neglected;

more diets must be fitted and fewer handed out ready made.

A good history will often show that the diet is probably not the cause for the patient's discomfort. Patients must not be left too long on narrow elimination diets; such diets are for testing and not for treatment.

Some cases of diarrhea and pseudo-ulcer are due to the milk that is taken by way of treatment, and not infrequently certain foods irritate or greatly depress the brain. Somnolence after meals can be due to a particular food, and canker sores in the mouth can be produced by food.

Efforts to use an elimination diet are often instructive in showing the physician that he is dealing with an unreasonable, overly fussy, querulous, or psychopathic person.

Food sensitiveness is not necessarily allergic or due to protein. Perhaps partly for this reason, skin tests are of little help in finding the foods that cause indigestion.

DISCUSSION

DR. ARTHUR F. COCA (Pearl River, New York): Food sensitivity is limited to the group of familial or atopic allergy in which are associated hay fever, asthma, the urticaria due to foods, atopic dermatitis, gastro-intestinal allergy, migraine and others.

In the typical case (such as hay fever) antibodies—those peculiar atopic antibodies of the human being—are regularly demonstrable in the blood and indirectly through the positive skin test. The positive skin test appears only when these antibodies are present in the blood. They are often entirely absent, for some reason that we do not understand; in such cases the skin test results negatively.

Food sensitivity can be at the bottom of any of these many clinical varieties. Some of them are associated with a positive skin reactivity and others not. If the clinical form of the food sensitivity is asthma or hay fever, or atopic dermatitis, the skin test is quite regularly positive.

I have included atopic dermatitis (neurodermite) among the clinical varieties of food sensitivity in which the skin test is frequently positive. This statement must be considerably qualified by the further remark that the direct skin reaction in this condition is almost always so weak that it cannot be used diagnostically. However, a means has been developed by Matthew Walzer in Brooklyn of magnifying this weak reaction in a way to make it a thoroughly practical and reliable specific test. This means is the indirect test, which is performed with the technic of Prausnitz and Kuestner. The test is carried out as follows:

Serum is obtained from 5 to 10 c.c. of the blood of the patient by aseptic defibrination and centrifugation. One-twentieth c.c. of the serum is injected intracutaneously in about 50 well-separated sites in the upper arm of a substitute, who must not be allergic. Three days later these injected sites can be tested with the intracutaneous method with the usual food extracts, an identical control injection being made in a normal skin site in the same skin. In comparison with the negative result of the control test, slight degrees of reaction can be recognized as diagnostic which could not be accepted as significant in the direct test in the patient's skin.

By this means, Dr. Walzer states, about 60 per cent of subjects of neurodermite can be relieved by the avoidance of the indicated foods.

Notwithstanding the valuable contribution of Dr. Walzer to the technic of skin tests in the development of his indirect test, it still remains true, as Dr. Alvarez says, that in many cases of food sensitivity, especially urticaria, allergic headache and gastro-intestinal allergy, the skin test is of very little use. It is in such skin-negative cases that the physician must fall back on the trial diet plan.

The trial diet plan can succeed only if we possess a criterion of reactions, like the wheal in the skin test, that is diagnostically significant. The criteria under the trial diet plan are, of course, the clinical symptoms of food sensitivity. Such symptoms may be immediate or delayed. Immediate symptoms are gastric pain, headache (which may occur within a hour after the ingestion of the offending food), swelling of the lips in some instances, and a peculiar sensation of the mucous membrane of the tongue, which can be very acute. Vomiting is seen in some cases. The more violent symptoms should be avoided, if possible, by administering at the first trial only a small quantity of the food to be tested, where such symptoms are feared.

I have for some time been making use of another immediate symptom which seems heretofore to have been overlooked. This is tachycardia. I do not know how often this appears. It happened to be prominent in the first four cases of food allergy that I have had occasion to study. The symptoms in all these cases were gastro-intestinal or migraine. The tachycardia can range from a rate of 80 or 90, lasting for some hours after the ingestion of the offending food. In one case that had recently suffered a coronary thrombosis, the pulse rate has risen to 160 or 180 or more within a half hour after the injection of minute quantities of the offending substance. Three of these cases could be completely relieved of their symptoms by elimination of foods through the use of the criterion of tachycardia.

Delayed symptoms are more difficult to use as criteria of reactions. These are urticaria, diarrhea, bleeding from the intestinal tract. (This latter symptom may be more frequent than is generally known because patients are not advised to examine the stool for gross evidences of bleeding). Dizziness is a delayed symptom; also extrasystole, which may be the sole symptom of food allergy in some cases. A feeling of lassitude is a distinct delayed symptom in some cases.

In the application of the trial diet principle, all plans heretofore recommended have exhibited a common error which may explain some, at least, of the many failures encountered in the use of this principle. This mistake is the illogical one of trying more than one food at a time. Different allergists recommend different combinations of food in the initial test. The successes under all these plans represent merely those lucky individuals who happened to be sensitive to relatively few foods which were not included in the first selection.

Another circumstance which has no doubt interfered with the successful application of the trial diet principle is the fact that there are allergenic foods which have not been recognized as such by even the allergists. Among these may be mentioned gelatin, which, according to the chemists, contains no native protein but which, nevertheless, can be a violent food allergen. Another allergenic food that has been largely overlooked is sugar, both from cane and from beet. There is relatively very little protein in sugar. When the protein is collected out of a solution of sugar by the process of ultrafiltration, it is found that there is something over 100 milligrams of it in 200 pounds. On the basis of the established fact that about 1 per cent of negative protein in solution will find its way through an ultrafilter when the ultrafiltration has proceeded for a period of about 48 hours, I have been able to calculate that 1/100,000 of a milligram, or possibly less, of sugar protein may cause disagreeable allergic symptoms (tachycardia, dizziness and headache) when that quantity is given daily over a period of two days.

The logical plan of applying the trial diet principle must be, first, to withhold all food until the symptoms disappear and, secondly, to administer one food at a time in ample quantity, each food being added only after the preceding

but which in reality probably represents a small acute transient process in the course of the slowly progressing degenerative, sclerotic or infectious process which is called "chronic pancreatitis."

As regards treatment, pancreatic ferments by mouth, the minimizing of infection elsewhere and the proper diet, especially one limited as to fats, unquestionably help certain of these cases. I have always felt in this connection, that it is probable that in certain cases of cholecystitis, with or without stones, the benefit that follows from a fat low or fat free diet is not all due to its effect upon the biliary infection, but is rather due to the effect of this diet upon the associated pancreatic disease or dysfunction so frequently associated with gall bladder disease. In my experience, if gall bladder disease, even cholelithiasis, is not associated with jaundice or pancreatic trouble, the simpler fats, butter, cream, olive oil and especially egg yolk are in reality our most valuable dietetic aids in promating gall bladder drainage and should be used in large amounts.

Are there *functional disturbances* of the pancreatic external secretion? There must be, for the pancreas is supplied with autonomic nerves which unquestionably play some, if not the major, *rôle* in stimulating or inhibiting secretory activity and therefore there certainly must be examples of hypo-, hyper-, and achylia-pancreatica of this origin. But its diagnosis is obviously extremely difficult; probably in most cases impossible, for while we may suspect it, it is very hard to differentiate from mild chronic pancreatitis, just as it is equally difficult or impossible to differentiate certain functional gastric disturbances from a mild gastritis, although the gastroscope may settle this question.

I have seen a few cases, however, in which I think the diagnosis was absolutely justified. Let me report one—a woman who had been operated upon many years ago and eighteen gall stones removed from the gall bladder. When seen by me fourteen years later, she had definite recurrent gall stones attacks and I had her operated upon with a removal of the gall bladder filled with stones. The pancreas was found perfectly normal at the time but a few days after the operation she developed an intractable diarrhea with typical butter stool and complete absence of pancreatic diastase and trypsin. Time, diet, possibly helped by the administration of pancreatic extract in large amounts, cleared up the condition; in a relatively short period of time, the diarrhea stopped, the stool regained its normal character. That the pancreatic trouble was purely functional, I think was shown beyond question not only by the rapid return to normal of the stool and the reappearance of pancreatic ferments in the fecal material, but by the fact that in a subsequent operation made about three months later for adhesions, the pancreas was examined carefully and found to be just as normal as it had been at the time of the preceding operation. If diarrhea follows cholecystectomy, as it does in a very small proportion of cases, it is probably often of this origin.

In thinking over the problems of the pancreas, one cannot fail to ask himself certain questions not answered in this rapid survey of our experience in this field. The most important is—is the pancreas an absolutely essential organ? Apparently not as regards its external secretion for proteolysis can be brought about by the pepsin and hydrochloric acid of the stomach, the erepsin, and possibly other ferments of the small intestine, and possibly by bacterial action. There is diastase from the salivary glands with minimal amounts from Brunner's glands and the bile to carry on starch digestion. The fats, however, will fare rather badly for lipase is derived almost exclusively from this organ and fat digestion is practically always impaired in extensive pancreatic disease or dysfunction. But, after all, good health may be maintained on a high carbohydrate, high vitamin, normal protein, low fat diet.

There is clinical as well as experimental evidence that the pancreas is not absolutely essential. Functional pancreatic achylia with its butter stool, if treated with the proper diet, does not seriously affect the general health. Even in organic conditions where there is complete absence of this secretion, such as in a few cases of tropical sprue, a certain number of cases of cirrhosis and many cases of carcinoma of the head of the pancreas, death does not come early but at long last. Certainly in cases of carcinoma of the pancreatic head, the symptoms in the early stages—malaise, depression, pruritus, chills and fever, even pain—are not due to the cancer *per se* but are symptoms of a progressive jaundice with biliary toxemia. Thus the marvelous temporary improvement after cholecyst -gastrostomy or -duodenostomy! There is experimental evidence also in favor of this. For instance, in 1912, in a series of experiments made upon dogs with pancreatic fistulas, we found that as long as they were given plenty of fluids and plenty of alkali, their condition remained extremely good for a long period of time. If, on the other hand, the common biliary duct was subsequently ligated and a complete obstructive jaundice produced, in every case this was followed immediately by rapid loss in weight and strength and early death, emphasizing anew the great importance of the bile as a partial substitute for the pancreatic secretion if the latter is absent or markedly diminished.

These findings — clinical and experimental — are really of great significance for they justify partial or complete pancreatectomy for carcinoma. The salivary, gastric and intestinal secretion, and bile, possibly helped by pancreatin by mouth, will act as substitutes for the external secretion; insulin, possibly some day, pancreas transplantation, for the internal secretion.

Is pancreatic disease more common than is supposed or diagnosed? I am sure so. Can it be recognized or suspected more frequently than at present? I believe so, if one but keeps in mind its possibility in all cases with vague upper abdominal symptoms, with and without pain, and then utilizes all possible diagnostic procedures.

Perhaps there is no better way to end this fragmentary talk on the clinical aspects of pancreatic disease than to repeat what was said by Sir Archibold Garrod many years ago—"The chief difficulty in diagnosing disease of the pancreas is in thinking of the pancreas."

Surgical Aspects of Diseases of the Pancreas*

By

DANIEL F. JONES, M.D.
BOSTON, MASSACHUSETTS

IN a paper read before the New England Surgical Society in September, 1921, on "Acute Pancreatitis," I said that the term would probably always be used but that I would try to show that it was not descriptive enough and that the terms *acute pancreatic necrosis* or *acute hemorrhagic necrosis of the pancreas*, and *acute and chronic interstitial pancreatitis* would describe the various conditions found more accurately. I can find no reason for changing this opinion in spite of the fact that no one seems to have followed my suggestion.

Archibald (Lewis' "Practice of Surgery") has helped matters very much by dividing pancreatic cases into six groups, as follows:

(1) *Hyperacute pancreatic necrosis.*
(2) *Acute pancreatic necrosis.*
(3) *Subacute pancreatic necrosis.*
(4) *Acute pancreatic oedema.* (Zoepffel)
(5) *Chronic pancreatitis with recurrent subacute attacks.*
(6) *Chronic pancreatitis with sclerosis* (following acute attacks).

So far as dividing these cases into definite groups is concerned, this classification is of value, and if it were properly used we should not have such variation in the mortality statistics under the heading of acute pancreatitis as we have at present, when it varies from 22.7 per cent to 70 per cent or more. This great variation in mortality must be due to the variation in the type of cases used rather than to the difference in the skill of various surgeons.

My objection to this classification is that I believe there are two types of pancreatitis:

(1) Acute pancreatic necrosis, due to injury to the pancreatic ducts by retrojection of bile or duodenal contents into the pancreatic ducts, causing a digestion of the pancreatic parenchyma.

(2) An infiltration of the interstitial tissue with enlargement and an increased hardness and at times oedema. The condition may be either acute or chronic. The parenchyma of the gland is not involved. This should be known as interstitial pancreatitis.

With an idea in my own mind that the classification, etiology, pathology, symptomatology, and treatment of pancreatitis had been clarified to some extent, I was much disturbed to find that there was more confusion than ever about these points. It is impossible to discuss these cases until we can at least agree upon some classification, and classification cannot be agreed upon until the pathology has been agreed upon. Archibald has classified the cases of pancreatic necrosis, but what constitutes a pancreatitic necrosis? I have classified as pancreatic necrosis any case of pancreatitis in which there is fat necrosis or hemorrhage, because it is my belief that neither occurs without the release of activated pancreatic secretion which in turn causes pain and tenderness in the upper abdomen with nausea.

Archibald has a group which he calls chronic pancreatitis, which is due apparently either to very mild repeated attacks of pancreatic necrosis or to repeated attacks caused by the backing up of nearly normal bile into the pancreatic ducts, which he calls "subacute attacks of pancreatitis." He has still another group which he calls chronic pancreatitis with sclerosis, due to acute attacks of pancreatic necrosis, I assume, as only a necrosis could cause the amount of destruction he speaks of.

It has been my contention that there is an interstitial pancreatitis without involvement of the parenchyma, due to infection of the interstitial tissue. There are many cases of so-called interstitial pancreatitis of which there are no symptoms at any time, unless an abscess is formed and that seldom occurs. It is found only during the course of operation for other causes, such as cholelithiasis, peptic ulcer, or abdominal infection.

Three articles have been published recently in which various pathological changes have been classified under chronic pancreatitis and chronic interstitial or interlobular pancreatitis. Hinton (Annals of Surgery, September, 1932) states that duodenal and gastric ulcers in contact with the pancreas cause interlobular pancreatitis, which causes severe pain relieved at once by gastro-enterostomy. DeTarnowsky and Sarma (Annals of Surgery, June, 1935) describe *chronic pancreatitis* as a thickening of the gland due to repeated attacks of acute subsiding pancreatitis. Elman (Surgery, Gynecology, and Obstetrics, Nov., 1935) confuses the matter still more by reporting six cases of chronic *interlobular* pancreatitis, three of which had fat necrosis and three of which had no fat necrosis but had gall stones.

Under such conditions how is it possible to discuss chronic interstitial pancreatitis intelligently? I can only say that I myself have never seen a case of "chronic interstitial pancreatitis" without hemorrhage or fat necrosis diagnosticated before operation. Such conditions have no symptoms so far as I can determine.

The *mortality* of the two groups, acute pancreatic necrosis and chronic interstitial pancreatitis, is strikingly different. There is a mortality of at least 50 per cent in the cases in which the parenchyma is involved, while in the second group the mortality cannot be more than 2 to 3 per cent. If we accept Archibald's classification of acute pancreatic oedema (Zoepffel) as an acute interstitial pancreatitis, this would bring up the mortality rate somewhat. If, however, it is classed as acute pancreatic necrosis, as I believe it should be, the mortality rate corresponds accurately to the mortality rate of the acute pancreatic necrosis group.

*Delivered at the Thirty-ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936.
Approved by the Publications' Committee.

Not only are these two groups different in pathology, etiology, and mortality, but the two have entirely different symptoms. In the first group the patients are always operated upon because of symptoms due to the pancreatic necrosis or retrojection of nearly normal bile, while in the interstitial pancreatitis group they are operated upon because of symptoms due to biliary disease, duodenal or gastric ulcer (Hinton), or abdominal infections.

If we accept the division of these cases into the two groups, (1) acute and chronic pancreatitis due to activated pancreatic secretion or nearly normal bile, and (2) interstitial pancreatitis probably due to infection of the pancreas, and accept Archibald's division of the pancreatic necrosis cases into four groups, we can talk about the operative procedures and mortality of each.

There is some difference of opinion in regard to the type of operation to be performed. Archibald believes it necessary only to drain the biliary system. This appears logical, but what of the four autopsies reported by Opie some twenty-five years ago, in which the necrosis was limited to the area drained by the duct of Santorini which opened separately into the duodenum. While it is logical to drain the biliary system, there are undoubtedly a certain percentage of pancreatic necrosis cases due to retrojection of bile into the duct of Santorini. In fact, Opie states that the duct of Santorini is the main duct in 10 out of 100 autopsies.

The operative procedures for the various divisions of Archibald's classification should be settled in the minds of all surgeons. The extent of the operation should be determined by the condition of the patient. The very sick should have the least possible done; that is, drainage of the fatty capsule. If the surgeon believes it reasonable, a cholecystostomy with or without removal of stones may be done. Those in slightly better condition should have the fatty capsule and the true capsule, where soft areas are found, drained and a cholecystostomy done with removal of gall stones. In those patients in still better condition the gall bladder should be removed, the ducts explored, and a choledochostomy done.

It is self evident that drainage of the common duct will give freer flow than will drainage through the gall bladder, but it is necessary not infrequently to do a cholecystostomy because of the condition of the patient or because of the difficulty of reaching the duct.

Archibald does not approve of cholecystectomies for fear that the gall bladder may be needed for drainage later, but the great majority of surgeons do remove the gall bladder if the condition of the patient will permit it.

It is difficult to see the objection to drainage of the fatty capsule when it is infiltrated and tense and contains much broken down tissue. While I agree with Archibald in practically all of his work, I cannot agree that drainage of the biliary system is all that is necessary. I feel strongly that drainage of the fatty capsule, and the true capsule of the gland so far as it can be done without injury to the pancreas, is of great advantage to the patient. I have seen many patients relieved of pain and shock after drainage of the fatty capsule, and have had two very definite cases in which the patient remained uncomfortable, nauseated, and unable to eat after biliary drainage without drainage of the fatty capsule. Both were comparatively mild cases and both recovered after ten days which were very trying both to the patient and to the surgeon. I have never since neglected to drain the fatty capsule when there is swelling in the region of the pancreas, fat necrosis, or hemorrhage, no matter how slight.

It is true that drainage of the fatty capsule is more likely to cause an infection of the fat about the capsule than no drainage, but on the other hand proper drainage at the primary operation may prevent a secondary operation for the drainage of an abscess in this region. The neglect of early drainage of abscesses may, I believe, be responsible for some of the late deaths. When the fatty capsule is drained early, the patient frequently runs a moderate temperature or none at all for a week or ten days, at the end of which time the temperature rises to 101° or 103° with increased discharge of pus, broken down fat, and necrotic gland. A secondary operation is frequently necessary to give better drainage unless a large drainage wound is left at the first operation.

In addition to the difficulties of post operative drainage of the fatty capsule, these conditions not infrequently cause thrombosis of the veins in this region, not only the splenic vein but even the vena cava. The sepsis which is often present may cause infection in other regions, the same as any abdominal infection.

There have been changes in the minds of some surgeons recently in regard to the best time for operating on cases of acute pancreatic necrosis, largely because of the high mortality in these cases with our present method of so-called "early" operation. But are there enough cases operated upon within twenty-four hours to give us a proper idea as to the value of early operation? At the Massachusetts General Hospital early operation has largely been given up.

DeTakats and MacKenzie (Annals of Surgery, September, 1932) believe that:

(1) "Patients should never be operated upon in the initial shock," and yet their statistics show that the mortality in those cases operated upon within 24 hours is 25 per cent, the lowest mortality except for the group operated upon more than three weeks after the onset of symptoms. It may not be proper to operate within 2 to 6 hours after the onset, but it is a well known fact in surgery that removal of any condition causing shock will frequently save the life of the patient. The surgery must, of course, be reduced to a minimum. It is my belief, therefore, that all cases of pancreatic necrosis except the very mild should be operated upon at the earliest possible moment, first because of the possibility of an error in diagnosis, and secondly because I believe that there will be less destruction of tissue, and that the operation should be carried out under local anesthesia with a minimum of ether to keep the patient on the table during manipulation.

(2) "If all diagnostic measures point to pancreatic necrosis, delay is permissible until abscesses localize, cysts and gangrenous parts need removal." Yet their statistics show that operations delayed over 24 hours and up to 3 weeks have a mortality of 50 per cent. It is, I believe, important that all cases except the very mild ones be operated upon within 24 hours if it is possible to get the cases.

(3) "If diagnosis is uncertain, early operation must be done for fear of overlooking intestinal perfora-

tions." Operation within 24 hours would cover these cases.

(4) "If the attack is mild, wait for recovery and then diagnose and operate for biliary tract infection." Their statistics show that the mortality in cases operated upon more than 3 weeks after onset was only 20 per cent. It is quite evident that these cases were mild or operation would have been performed earlier. It would seem that the mortality of cases operated upon from 2 to 3 weeks after onset, 66 per cent, and the mortality of those operated upon after 3 weeks, 20 per cent, were unnecessarily high. It would seem reasonable to expect a lower mortality if all operations had been done within 24 hours.

May I diverge for a moment to mention *diagnosis* and to say that laboratory examinations, at least those in use up to the present time, should not make one give up physical examination, for every available method should be used in the diagnosis of these difficult cases. The most satisfactory aid to making such a diagnosis is the careful determination of the location of tenderness. It is not enough to say that there is tenderness in the upper abdomen. Given symptoms suggesting gall bladder disease, the diagnosis of pancreatitis should be made correctly in a high percentage of cases if there is tenderness extending to the left from the gall bladder. This can be accomplished only by meticulous care as to the amount and extent of the tenderness. Experience is necessary, of course, to make this distinction and yet a former resident, of very moderate hospital experience, made a correct diagnosis in the next two cases that were admitted after he had been taught this method of diagnosis.

I appreciate that there has been much written recently about attacks of pancreatitis causing pain, indigestion, and discomfort in the upper abdomen after cholecystectomies and cholecystostomies, but I have not seen enough of these cases to make me feel that pancreatitis following cholecystectomy and choledochostomy is of much importance. It is true that at operation I have left stones which have had to be removed at a second operation, but this has always given relief. I have operated twice for attacks of pain following operations for gall stones without finding any cause for the pain, even pancreatitis, but in spite of this there was no further occurrence of the pain after several years.

It is quite evident from various case reports that there is frequently more than one attack suggestive of pancreatitis before operation seems necessary. In 1921 I called attention to the fact that 22 of the forty-three cases of acute pancreatitis from the Massachusetts General Hospital occurred in patients without gall stones, and of these 17 had had one or more attacks of pain before having an acute attack of pancreatic necrosis requiring operation.

Archibald believes the mild attacks to be acute pancreatitis due to retrojection of nearly normal bile into the pancreatic duct, which causes an inflammation and therefore swelling, but not a necrosis. Whipple and Goodpasture (Surgery, Gynecology and Obstetrics, 1913, XVII, 591) report that in animals there may be attacks of pancreatic necrosis with absorption of the necrotic material which leave a scar so small that it is difficult to find it. How such a condition can produce the findings of deTakats and MacKenzie is difficult to understand.

"Indigestion" and slight discomfort in the epigastrium do not have much significance for me. When we consider the various operations which have been carried out for the relief of these symptoms, we wonder if these symptoms really mean much. The outstanding reasons given for such symptoms before operation have been chronic appendicitis, chronic salpingitis, retroversion of the uterus, so-called chronic cholecystitis without stones together with an X-ray showing a gall bladder which does not empty quite as the roentgenologist thinks it should, stasis in the duodenum, duodenal diverticulum, and now chronic pancreatitis either before or after operation. One is not much impressed with the value of these symptoms when they are supposed to be "cured" but such different operations. In many clinics chronic cholecystitis without stones makes up at least 50 per cent of all the gall bladder operations. One wonders why we do not all have our gall bladders out for slight indigestion and perhaps a fulness in the upper abdomen. It has been said by some surgeons that cases of chronic choecystitis without gall stones should be operated upon not only for relief of "indigestion," but also for fear they may cause pancreatitis! In spite of this great danger, Wilkie has said that he has had great difficulty in finding a bacteriologist who could find bacteria in the gall bladder walls for him, and yet he considers operation of great importance. If these symptoms are of value, why has it been necessary to do so many different operations for the relief of them, and why are patients not more often relieved by the operations?

Operations for the relief of acute interstitial pancreatitis do not seem to be necessary as the symptoms do not seem to be sufficient to make a diagnosis possible, or at least to make an operation necessary, as such a condition is rarely if ever seen at operation unless we consider Zoepffel's acute oedema of the pancreas as an acute interstitial pancreatitis.

The treatment of chronic interstitial pancreatitis is incidental to finding it in the course of operations for other conditions such as cholelithiasis, duodenal or gastric ulcer, acute cholecystitis, or some abdominal infection, and should consist, I believe, of the removal of whatever is the cause of the pain. To make doubly sure, it is important to drain the biliary system especially if there is jaundice. Many cases of chronic pancreatitis have been relieved entirely by cholecystectomy alone, without drainage of the biliary system. Long continued drainage of the biliary system has been emphasized by many surgeons, especially Deaver, but drainage for two weeks is sufficient in all the cases I have seen. Deaver recommended and carried out on several patients cholecyst-gastrostomy in cases in which jaundice had recurred or had not cleared. It has been my good fortune in about 2500 cases of cholelithiasis and cholecystitis never to have been obliged to do a cholecyst-gastrostomy for chronic interstitial pancreatitis. It seems probable that when any such operation is necessary, the condition present may be carcinoma of the head of the pancreas.

As to *preventive measures* in pancreatic disease, there is no doubt but that removal of gall stones when found is an excellent measure, but I cannot agree with those who feel that it is important to remove the gall bladder in cases of so-called chronic cholecystitis without stones, to prevent acute or chronic pancreatitis. The arithmetic of these men seems to me to be at

fault, for in my own practice I have operated upon forty cases of acute pancreatic necrosis and abscesses of the pancreas, while during the same period I have seen more than 2500 cases of cholelithiasis. That is, about 1.6 per cent of all the cases of cholelithiasis and acute cholecystitis are associated with acute pancreatic necrosis.

As the mortality of acute pancreatic necrosis is about 50 per cent, the mortality rate for these acute pancreatic necrosis cases associated with cholelithiasis and acute cholecystitis could not be more than 0.8 per cent. The operative mortality for cholecystectomy in cases of chronic cholecystitis could not be less than 2 per cent, which leaves a balance of 1.2 per cent in favor of not operating upon these cases.

While it must be admitted that there is little that is new in regard to the *treatment* of pancreatitis, we have a most brilliant piece of clinical work on carcinoma of the pancreas, for which we owe a debt of gratitude to Drs. *Whipple, Parsons, and Mullins, regardless of* whether the late results will or will not be commensurate with the brilliancy of the clinical deductions that have been made.

It must have been appreciated by every surgeon that pancreatic secretion could not get into the duodenum in cases of carcinoma of the head of the pancreas with marked jaundice, yet no one has ever before drawn the conclusion that the pancreatic duct might be tied off without doing any damage to the individual. This clinical observation has brought many cases of carcinoma of the pancreas into the field of operative surgery. Not only is the observation and proof that the patient can exist without the external secretion of the pancreas of importance, but the carefully worked out operative procedure is of great importance. (Whipple, Annals of Surgery, October, 1935).

It has taken many years to convince surgeons that the pancreas can be operated upon the same as any other organ, provided one is careful to prevent leakage and infection. In fact, it has been found that the pancreas can be incised or large sections removed without danger to the patient. To have this proof that patients can live with the pancreatic duct tied off gives the surgeon control over the whole pancreas. A large part of the tail can be removed from the tail toward the head without doing harm, and now that Whipple, Parsons, and Mullins have proved that the pancreas can be partly removed from the head toward the tail, the whole organ is under control.

Not only is this work of importance in carcinoma, but it will make the removal of cysts much more certain than formerly. Removal of a portion of the pancreas with the cyst may be done with the hope of no further trouble, for few have attempted to remove cysts of the pancreas with any feeling of certainty that they would not recur. With our present knowledge of the pancreas, removal of sufficient gland tissue to make sure that a cystadenoma or a simple cyst will not recur is of importance. Degeneration cysts or pseudocysts should not recur, and simple drainage is all that is necessary.

Probably the most spectular operations on the pancreas are those for hypoglycaemia due to adenomata or to hyperplasia of the pancreas. In addition to the adenomata, which give such striking results when removed, there is apparently a hyperplasia similar to hyperplasia of the thyroid gland. Some cases have been operated upon in which no adenoma can be found. In order to treat these cases, an unexpectedly large proportion of the gland must be removed, as in thyroidectomy, in order to reduce the insulin sufficiently to return the patient to normal. Unfortunately the problem is more difficult than in thyroid disease because of the greater risk in opening the abdomen two or more times to reduce the gland sufficiently.

In all operations for removal of a large or small part of the pancreas the great danger is in injury to the blood vessels in the region of the pancreas. Removal of the spleen may be necessary because of injury to the blood supply or to facilitate the removal of a growth.

The operation for hypoglycaemia and Whipple's operation for carcinoma of the pancreas have been the outstanding clinical advances in surgery of the pancreas in many years. Let us hope that within the next ten years the etiology, classification, diagnosis and treatment of pancreatitis can be put on a more definite basis than it is at the present time.

Thoracic Stomach with Short Esophagus and Diaphragmatic Hernia*

By

LEON BLOCH, M.D., A. M. SERBY, M.D.

and

SAMUEL SALINGER, M.D.

CHICAGO, ILLINOIS

"DIAPHRAGMATIC hernia" was the all inclusive term applied to a protrusion of the stomach through the diaphragm, until Bailey (1) introduced the name "thoracic stomach" to that type due to a shortening of the esophagus. There is a tendency to ascribe all of these lesions to a congenital, actual or potential defect in the diaphragm in contradistinction to the traumatic form of hernia through the diaphragm. A potential widening of the hiatus esophageus may, however, be a predisposing factor in the causation of the latter. In three patients of our series, an hiatus large enough to admit three fingers was found at the time that an operation was being performed for some other condition. Where formerly

* Delivered at the Thirty-ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936. Approved by the Publications' Committee.

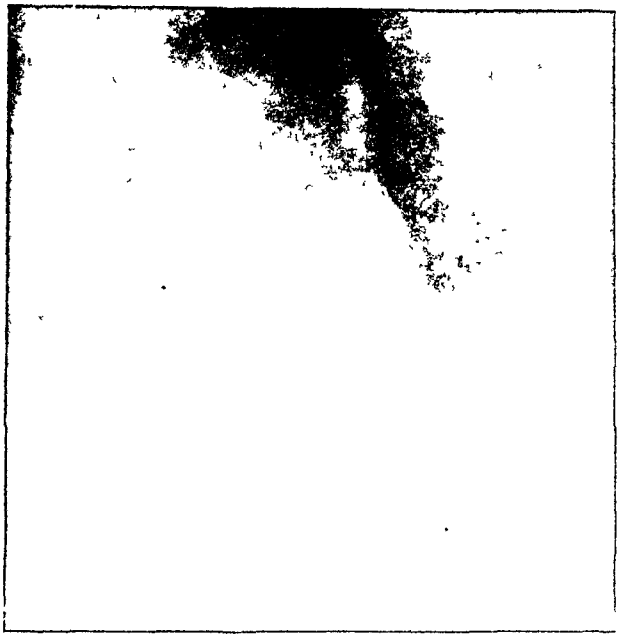

Fig. 1

diaphragamatic hernia was considered to be the more frequent lesion, it seems that the diagnosis of hiatus hernia and congenitally short esophagus is gaining in ascendency. An adherence to Akerlund's (2) classification of three types would help to clarify the situation immeasurably. There will be however, because of a lack of diagnostic methods, a large number of cases which will be unclassifiable.

Our interest in this subject was aroused by the fact that we were encountering these lesions in greater numbers, undoubtedly due to an increasing number of reports in the literature, and an increasing ability to recognize them. Therefore, when we decided to study this condition more thoroughly, we recalled as many of our patients as we could, in whom the diagnosis of "diaphragmatic hernia" had been made previously, with the purpose of trying to differentiate them into recognizable types. As we were only partially successful in our attempt, one of us enlisted the aid of esophagoscopy and later biopsic examination as suggested by Clerf and Manges (3). It is quite obvious that this kind of examination is superior to that of localizing the length of the esophagus by the level of the thoracic vertebra, although the latter is a much simpler procedure. Unfortunately we were unable to obtain the consent of all the previously examined patients to return for another fluoroscopy and still less for esophagoscopy. While we were thus enabled to increase our ability to differentiate the types, we did not acquire a corresponding increase in our facility to make a clinical diagnosis of the condition beforehand. On several occasions we suspected the lesion, only to find ourselves wrong in the majority of cases. We are inclined to agree with Ritvo (4) that in the majority of the cases it is an accidental finding without characteristic symptoms. The symptoms related by the patients are more frequently due to some other underlying cause. If more individuals were examined roentgenologically, the lesion would undoubtedly be found more frequently.

Incidence: Eleven patients were males and twenty-seven females. All of our cases were in adults. The ages ranged from 31 to 70. Only seven of these were in the seventh decade of life.

Symptoms: A restatement of the symptoms will be nothing new. We shall therefore make an analysis of the symptoms encountered in the hope of finding out which ones, singly or in combination, might suggest a diagnosis before other methods of investigation are utilized.

Twelve complained of epigastric pain, for periods varying from one to twenty-four years. In three of these the pain was worse at night, or on lying down, and in four it radiated to the left. One patient stated that the pain was distinctly worse on attempting to lift a heavy weight, Fig. 1. This patient, a woman of 51, was seen in 1933 because of pain in the right upper quadrant of the abdomen of eight years duration. She had some pyrosis which was relieved by soda bicarbonate, but no dysphagia. The gall bladder concentrated the dye normally. We mention this negative point because on X-ray examination a narrowing of the esophagus was found in addition to a large supradiaphragmatic gastric pouch. She came to the hospital for esophagoscopy and then changed her mind. This is probably a case of thoracic stomach on the basis of a congenitally short esophagus.

In the four patients whose pain radiated to the back, the lesion was of medium size in two, large in the second, and small in the third. In the last patient the esophagosopic length was 40 cm. and biopsic examination revealed esophageal tissue at that distance. The impression obtained, therefore, is that this might well be a case of para esophageal diaphragmatic hernia, which incidentally is the impression obtained on fluoroscopic examination. Another patient, female, age 51, with a medium sized gastric pouch had complained of severe pain in the left upper quadrant radiating to the back for many years—in fact as long as she could remember. The pain came on immediately after meals and was made worse by a heavy meal. Occasionally

Fig. 2

the pain occurred at night. The gall bladder concentrated the dye normally. The esophagoscopic length was 40 cm.

The mucosa at the cardiac orifice was reddened. Biopsic examination revealed gastric tissue. This is probably another case of para esophageal hernia. Three of these twelve patients had cholelithiasis.

"Heartburn" occurred in twenty-two patients, in seven of whom it was relieved by soda bicarbonate. In eight, it was definitely worse at night or occurred only on lying down, to be relieved when the patient assumed an upright position. In three of these the lesions were of medium size and associated with esophageal constriction above the gastric pouch in two. In one of these, a patient, age 56, who was afraid to lie down because of heartburn, esophagoscopy revealed an hyperemic mucosa which bled easily, and a thickening of the posterior folds at a level of 32 centimeters. In spite of this definite picture of esophagitis, her only complaint was nocturnal pyrosis without dysphagia. Another patient, a male, age 11, complained of heartburn for about eighteen years, when lying down. X-ray examination revealed a large gastric pouch with an esophageal constriction. The esophageal length was 37 centimeters. The diagnosis is probably thoracic stomach with short esophagus.

Six of these twenty patients had cholelithiasis. How much the pyrosis was due to this and how much to the gastric lesion, is difficult to tell. In the majority of cases there was no relationship between the size of the lesion and the amount of heartburn.

Vomiting, alone or with regurgitation, occurred in ten patients, and regurgitation in four. Relief of the distress by vomiting was not common. In five of these patients the lesion was small, in two large and one medium.

Pain in the chest, either of a substernal type or radiating to right or left, occurred in only 6 patients. One of these patients came to see us in 1931 complaining of irregular gastro-intestinal discomfort. Two years before, a diagnosis of chronic cholecystitis was made in Detroit by very capable physicians. At times the patient complained of severe right hypochondriac pain. About one year later he had severe pain in the left precordial region, radiating to the left shoulder and arm. The gall bladder concentrated the dye well and an electrocardiogram showed no deviations from normal. A tentative diagnosis of diaphragmatic hernia was recorded on the history, but it could not be confirmed by X-ray examination. Four years later the diagnosis of thoracic stomach and short esophagus was made at the Mt. Sinai Hospital, New York, while the patient was under the care of Dr. Winkelstein. Hurst (5) reported the case of a patient with recurrent hernia of the stomach through the hiatus esophageus of the diaphragm with pain resembling angina pectoris. Three patients in this group had dysphagia, but esophagoscopy was unsuccessful in two and not tried in one. One other patient in this group will be discussed later. In two it was undecided whether the pain was referred into the chest from calculous cholecystitis, or from the gastric pouch.

A history of dyspnea was obtained in six patients. In all of these the lesion was either of medium or large size. Goodall and Hoyt (6) lay great stress on dyspnea of a peculiar type which occurred in four of their five patients. They found a characteristic dyspnea, one occurring on the slightest effort or after eating—a sort

Fig. 3

of panting breathing—disappearing when the patient sits down and prone to be absent even on exertion, when the stomach is empty.

They divide their cases in two types—one in which the major part of the stomach is above the diaphragm, and the other in which the major part is below the diaphragm. The intense type of this remarkable form of dyspnea occurs in the first type and lead the authors to make a clinical diagnosis of thoracic stomach in two other patients, after having found a thoracic stomach on X-ray examination in the first patient who had this sort of breathing. We did not encounter this severe symptom in any of our patients because the lesions were all of the second type, with the exception of one who refused to come back for a re-examination. Six patients complained of some form of dyspnea. One in this series, Fig. 2, a woman of 38, complained of epigastric pain, nausea, vomiting, tightness and a smothering sensation of the chest with frequent attacks of dyspnea. She had stomach trouble dating back to childhood. In 1926 she was told that she had asthma. An X-ray examination revealed the largest thoracic stomach in our series. Unfortunately we lost track of her and could not get her back for re-examination or esophagoscopy. In the light of Goodall and Hoyt's report and the fact that her symptoms dated back to childhood, we are inclined to consider this case as one of congenitally short esophagus and thoracic stomach.

Dysphagia occurred in six patients. In the report of Clerf and Manges (2) dysphagia was a prominent symptom. Their patients differed from ours in that the majority came to them primarily for difficulty in swallowing. The lesions were of medium size in two, small in three, and undetermined in one. Two had indefinite chest pain and three heartburn at epigastric

pain. Esophagoscopy was carried out unsuccessfully in three patients.

They refused to return for re-examination. X-ray examination revealed a supragastric constriction. One of the patients ,Fig. 3, male, age 62, had difficulty in swallowing over a period of two years and had had repeated attacks of biliary colic. X-ray examination revealed a thoracic stomach with an esophageal narrowing and cholelithiasis. A cholecystectomy was done, at which time it was found that the hiatus esophageus admitted three fingers quite readily. The dysphagia returned later. Esophageal dilatation gave him some relief. Esophagoscopy was attempted, but because he violated instructions not to partake of fluid and denied having done so, it was unsuccessful as gastric fluid regurgitated into the esophagus at the time of examination. He refused to return for re-examination.

In attempting to *evaluate these symptoms*, we were confronted by the fact that many of the patients who had other pathological conditions, as calculous cholecystitis (11 cases), hypertension with or without cardiac involvement (8 cases), hyperthyroidism (2 cases) and syphilis (2 cases), had the same complaints as those patients with thoracic stomach without these lesions. It is, therefore, very difficult to determine upon a symptom complex which is typical of thoracic stomach. The following symptoms are suggestive: increased pain or heartburn on lying down, pain in the chest radiating to the left or down the left arm and dyspnea, neither one of cardiac origin, and difficulty in swallowing of long duration in a patient in whom traumatic stricture, carcinoma of the esophagus or cardiospasm can be ruled out.

X-ray examination: In every case the actual diagnosis was made by X-ray examination. Attempts to visualize both the hernial protrusion and the esophagus as suggested by Einhorn (7) were unsuccessful in most cases. It was necessary to give the patient some more barium and visualize both structures at the moment of the passing of the barium. This should be an excellent method for differentiation. Unfortunately a second meal of a thick paste was not always successful. We classified our lesions as small, about 3 centimeters or less in diameter, medium 4 to 6 centimeters, and large 7 centimeters or more. Fifteen were small, eleven medium and eight large.

X-ray examination alone sufficed to make a diagnosis of para esophageal hernia in seven patients, in one of whom it was confirmed by a double meal, and in six by finding the esophagus to be of normal length. In one patient dilatation of the esophagus by X-ray was found and esophagoscopy revealed shortening. In six patients the finding by X-ray of a constriction of the lower end of the esophagus with a supradiaphragmatic gastric pouch suggested the presence of a short esophagus. Only one of these was confirmed by esophagoscopy alone, as the other patients refused to return for further examination.

Esophagoscopy was employed for the purpose of getting information about the condition of the esophagus, determining its length and later to obtain specimens of tissue at the level at which gastric mucosa was seen. It is ordinarily accepted that the distance from the teeth to esophagus is 40 centimeters. However, this may vary some with the heighth of the patient. In this report 39 to 40 centimeters are accepted as normal, except in those patients in whom a constriction is found at the lower end of the esophagus, in addition to roentgenological evidence of a supradiaphragmatic pouch of the stomach. Because of our inability to have all patients with this possibility return for esophagoscopy, we are unable to furnish any definite statistics on this point. Esophagoscopy was carried out in fifteen patients. In nine it was responsible for the diagnosis, and in six it confirmed the diagnosis made by X-ray.

The results of *biopsic study* in nine patients showed that gastric mucosa was obtained in three patients at a level where the esophagus should be, and esophageal mucosa in the others. Because of a constriction at the lower end of the esophagus in three cases, it was impossible to enter the stomach. X-ray examination, however, revealed the fact that the esophagus was constricted above a small protrusion of the stomach above the diaphragm. In some patients in whom the esophagoscope was passed to the 39 or 40 centimeter mark, there is still the possibility of the lesion being a paraesophageal hernia—that is, a real diaphragmatic hernia. Many more studies will be necessary to determine this fact. In all cases where a biopsy was made, the esophagoscopic diagnosis was confirmed. It seems unlikely that this method of examination is necessary except in extremely doubtful cases.

SUMMARY AND CONCLUSIONS

1. Thirty-nine patients were seen with the diagnosis of some type of thoracic stomach. In 7 the lesion was a paraesophageal hernia. This diagnosis was confirmed by X-ray examination and finding the esophagus to be of normal length. In one it was confirmed at fluoroscopy by a double meal. Many may question the frequency of this lesion, and rightly so, because of the tendency to consider most of them to be due to congenital shortening of the esophagus.

2. In nineteen the diagnosis was thoracic stomach due to a shortened esophagus. In six a constriction of the esophagus above the gastric pouch was seen. In 9 the diagnosis of short esophagus was made or confirmed by esophagoscopy. In one the history of difficulty in swallowing and finding a constricted esophagus by fluoroscopy, and in another the history of gastric disturbance from childhood on, without an esophageal constriction, were sufficient to make the diagnosis. In one patient the diagnosis was made elsewhere. In 12 it was impossible to determine the kind of lesion found.

3. A clinical diagnosis of thoracic stomach should be suspected in patients presenting the above mentioned symptoms over a long period of time, in whom other pathological conditions can be ruled out.

4. The thoracic stomach of unknown type requires more careful examination by various methods, as X-ray, double meal and esophagoscopy for differentiation.

5. Biopsy is only a confirmatory procedure and is unnecessary where esophagoscopy is satisfactory.

DISCUSSION

DR. JOHN H. FITZGIBBON (Portland, Oregon): Dr. Bloch did not mention bleeding as a complication of diaphragmatic hernia. I have seen over thirty cases, out of which group two patients have had severe hemorrhages and a history suggestive of peptic ulcer, but with no X-ray evidence of abnormality other than hiatal hernia. It is reasonable to assume that they were bleeding from ulceration in the herniated part of the stomach. Both responded well to ulcer management and are continuing treatment. The recurrence of ulceration without hemorrhage in these patients is something that should be given serious consideration. If stools are routinely examined, we shall find occult blood continuing over long periods in many. Secondary anemia is occasionally an outstanding feature.

Dr. Bloch's paper brings out the fact that hiatal hernia is rather common, and I feel that we should emphasize the importance of horizontal fluoroscopy. No gastro-intestinal X-ray examination is complete unless the patient is examined lying flat or with the head lowered. Upon taking a deep breath and straining, barium will be seen to "pop" up through the hiatus into the hernia. If this sort of examination is made routinely, particularly in people who have been suspected of having gall bladder disease or who have been operated upon for supposed gall bladder symptoms without subsequent relief, hiatal hernia will be found much more commonly than is generally realized.

DR. RALPH C. BROWN (Chicago, Illinois): Adding to what Dr. Fitzgibbon has said, I am convinced that peptic ulcer occurs in association with these hiatus herniae, possibly resulting from the ischaemia produced in the mucosa of the stomach at the point of constriction. I have seen massive hemorrhage in association with at least one such case, and in two other cases there was such a degree of perigastritis at the point of constriction of the stomach as to involve the esophagus in scar-tissue to such a degree as to produce obstruction which required dilatation.

I think the probable association of peptic ulcer with hiatus hernia is something which at least should be kept definitely in mind. It is difficult to see the ulcer lesion when it exists at the point of constriction, so I am not able to state with absolute certainty that peptic ulcer occurred in the three cases to which I have referred. However, all three of these cases responded immediately and permanently to the therapeutic test of routine ulcer management.

DR. JOHN L. KANTOR (New York City): In addition to frank hemorrhage, there may be oozing in cases of diaphragmatic hernia. This is one of the causes of obscure anemia that should be kept in mind.

There was one case of this kind in New York that masqueraded as carcinoma. It was discovered by the late Dr. Rothschild, an internist. It is well worth knowing that by examining these people in the ordinary erect position and giving them a Sedlitz powder, one may bring out a second shadow parallelling the diaphragm but higher up in the chest. This shadow represents the gas filled intra-thoracic portion of the stomach. The procedure was devised by Dr. Ball and published in the *J. A. M. A.*, October 19, 1935.

DR. LEON BLOCH (closing the discussion): None of these patients had an apparent hemorrhage, but one had a definite ulcer which we could see with the esophagoscope very distinctly and bleeding had occurred. In all of the patients in whom esophagitis was found by the esophagoscope there was no question about the diagnosis: the mucosa was red, hyperemic, spongy and bled very readily so that undoubtedly had we examined the stool we might have found blood.

In two of the patients we found not only esophagitis but gastritis extending below the esophageal gastric margin.

The method of examination, of course, is important. All of the patients were examined, either lying down or in the Trendelenburg position. In most cases it is a simple matter to examine the patient in either the right or left oblique, or in the supine position. There was no difficulty in finding the lesion. Once in awhile we were aided in finding the lesion by having the patient take a deep breath, because when the diaphragm descended the gastric pouch came up very distinctly.

Specific Food Sensitiveness*

By

WALTER C. ALVAREZ, M.D.†

ROCHESTER, MINNESOTA

IN the time available I can report only briefly on some of the impressions that stand out strongly from the experience of the last few years. First, I would like to say that there is no question in my mind about the need for the development of a greater interest in specific food sensitiveness on the part of gastro-enterologists and, for that matter, of physicians practising in every field of medicine. We should all of us be grateful to the allergists for having opened our eyes to the possibility of relieving several distressing syndromes, such as migraine and mucous colitis, by the forbidding of certain foods.

Dietitians also could profit from conversion to the view that the *digestibility* of a food may at times be much more important to a patient than is its content of vitamins or calcium or iron. So far, most of the books on dietetics either ignore the subject of digestibility or else dismiss it with a few words, and the individual dietitian, unless she has been specially trained under an allergist, is likely to have little patience with anyone who claims that he cannot take milk or eggs or spinach or orange juice. Time and again highly allergic patients have told me of the miserable experiences they have had in hospitals where, after an operation, they were forced to continue eating the so-called "health foods" long after the prophesied vomiting or painful bloating appeared.

Perhaps I should say that the outset that I have no intention of joining the group of enthusiasts who seem to believe that nearly every disease is due to food allergy. Perhaps when I have learned more about this subject my percentage of miracles and cures will be higher, but as yet I must admit that I meet with far

*Delivered at the Thirty-ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936.

†Division of Medicine, The Mayo Clinic.

Approved by the Publications' Committee.

more failures and disappointments than with successes. In many cases I haven't even the desire to start experimenting with diet because the history suggests so strongly that the troubles are not due to the nature of the food eaten. This is particularly true when short spells of discomfort alternate with intervals of weeks or months when the patient is able to digest anything. In such circumstances, if the inciting factor were a food it would have to be one seldom eaten, and in such circumstances the patient would probably have recognized his idiosyncrasy. Or a woman with migraine will tell me that her headache comes only with menstruation or when she overworks or sits up late waiting to scold a wayward son, or when she takes a long automobile ride.

To be sure, in some of these cases migraine or vasomotor rhinitis may come as the result of the combined action of two insults, and the removal of wheat or some other food from the diet may enable the brain or the nose to withstand the effects of fatigue or menstruation or dust. Especially when, in a given case, facts in the history have warned the physician that the symptoms are probably not due to food, he will feel disinclined to keep on experimenting with narrow elimination diets unless they soon show definite signs of bringing relief.

Although, as I have said, I meet with more disappointments than miracles, when the miracles come they are so delightful that I feel that we physicians all owe it to our patients, to our reputations and to the good name of scientific medicine to keep constantly on the watch for cases in which remarkable successes can be attained.

Perhaps it would help if I were to stop for a moment to recount briefly three or four of the experiences which have convinced me that even those of us who are much interested in food sensitiveness must still be failing to recognize cases of the disease and must be turning away patients whom we could easily cure.

Thus, a few months ago, I saw with Doctor Rozendaal a young man who said that he was well until about seven years before, when he was a sophomore in college. He then began to have so much flatulence, abdominal pain, and mental cloudiness that study became almost impossible and he had to go home. There, in spite of treatment by many physicians, he continued to suffer so much that he could seldom do any work. My impression from looking at the man and listening to his story was that his mental deterioration was his part of a poor nervous inheritance which had produced a syndrome suggesting mild epilepsy in a brother, and I had no hope of helping him. All laboratory and roentgenologic reports were negative. It was only a forlorn hope that led us to experiment to see if an elimination diet would affect the abdominal distress. To our astonishment, he returned in forty-eight hours a different person. For years dull, apathetic and discouraged, he now was bright and wide awake, his ambition had returned, his head had become clear, his abdominal discomfort had disappeared, and he had begun to eat and to gain in weight. Soon he was able to work all day on his father's farm, and after a few months he wrote to say that his health was good so long as he avoided certain foods.

A physician was seen for several years with severe hunger pain, so typical of ulcer that it never occurred to me or to any of my colleagues to suggest a study of food sensitiveness. At times the pain was so severe that milk had to be taken every hour. Eventually the abdomen was explored, an ulcer could not be found, and pyloroplasty failed to give relief. In February, 1935, after an attack of asthma, skin tests were made and a tremendous sensitiveness to milk was discovered. Removal of this food from the diet brought immediate relief, and later it was found that orange juice and chocolate also had to be avoided. Since these three offending foods have been excluded from the diet, the patient has been perfectly well. I have seen now several such cases in which a desperate effort was being made to cure hunger pain with the very thing which was causing it; namely, milk!

For several years a man kept coming to The Mayo Clinic complaining of a sort of narcolepsy severe enough to cause him to fall asleep at the wheel of his car or while talking business in his office. All attempts at treatment had failed. Last year, when careful questioning revealed the fact that most of his trouble followed breakfast, I suggested that he go without this meal and then, if that helped, he could test one food at a time until an offender was found. I had little hope that he would find a cure this way and I had forgotten all about the man when, some months later, his home physician wrote that the avoidance of cream had worked a complete cure.

This brings me to another point that still deserves much emphasis, which is that *hurtful foods so often injure or irritate the brain.* To my surprise, once, while trying to cure hives in a man who had not worked for years on account of distressing feelings in his head, I accidentally cured the "insanity" and the man went back to take charge of his business again. On another occasion I saw a man in *status epilepticus* which was due apparently to his having gorged himself on strawberries, and I have seen people who knew that they would develop a vile temper if they ate certain foods. We all know that nightmares can follow the eating of a "Welsh rabbit," we know that splitting headache or migraine can follow the eating of chocolate or cheese, and I happen to know from personal experience that the eating of chicken or eggs can give rise to weird visions, annoying dopiness and even signs of meningeal irritation.

Besides the few cases in which a cure comes as a welcome surprise, there are, of course, the many in which it is to be expected because the patient has already learned that one or more foods will produce the symptoms complained of; he continues to suffer only because neither he nor his physician knows how to go about the business of discovering all of the noxious agents. If he is intelligent, all he needs to start him on the road to recovery is a little instruction in home detective work.

Obviously we cannot afford to waste time hunting for food sensitiveness in every patient, so the next question is: in what type of case should we be particularly careful to look for it? My impression now is that *we should look carefully for food sensitiveness* whenever the symptoms of abdominal distress point to the presence of an overly-sensitive colon, or when they are vague or unusual, or whenever careful examination fails to reveal any sign of disease in duodenum, stomach, gall bladder or appendix. We must study the diet in every case of true flatulence or bloating, and

we must look for food sensitiveness in some cases of migraine.

I doubt if it pays to study diet in every case of migraine because so often the history tells us that we are not likely to get anywhere along these lines. The headache may come only when the woman is menstruating or when she is very tired or has had an emotional debauch or we may see at a glance that we are dealing with a psychopathic or markedly asthenic person or one whose brain has been made so irritable by overwork, worry, grief or pain that the little "explosion" that causes the attack can take place every few days without the help of any extra insult, such as can be derived from food. This type of case is so common that I doubt if any large percentage of people with migraine can be relieved by dietary [illegible].

Occasionally I can help a patient with [illegible] but there are [illegible] whom I do not help [illegible]

[illegible]

[illegible] hours. This is to be expected from the fact that when a patient eats some harmful food the symptoms generally appear within a few hours. Accordingly, when a patient returns after having been for forty-eight hours on a narrow elimination diet and says that he is no better, the physician must not ask him to keep on for a month but must face the situation immediately. He must either accept defeat and tell the patient to return to his usual habits of eating, or else he must continue experimenting with substitutes in the elimination diet. If this does not help the patient can fast for a few days.

Ordinarily I start patients on a diet of lamb, rice, butter, sugar, and canned pears. If after a few days their distress persists, I may leave them for two days on nothing but maple sugar, or I may ask them to fast. If after this they still have their distress, I lose faith in my ability to help them with diet. Rowe tells me that sometimes in cases of wheat sensitiveness it takes ten days or a month to get the offending protein out of the system, but if it took me that long to help a patient with diet, I would suspect that the relief that came was due to some other factor such as rest, unconscious psychotherapy, or a spontaneous remission of symptoms.

Even when the elimination diet fails to help, it often gives much valuable and even decisive information as to the nature of the patient's troubles. Particularly in the case of women, one can learn so much from the way in which an individual faces or fails to face the little annoyances associated with the dieting. Often she frets so much, she acts so unreasonably, and she shows herself so irritable and so lacking in backbone and good sense that the diagnosis of "Fox's disease" can promptly be made. For those who are not acquainted with Fox's disease I will say that, one morning, [illegible] asked [illegible] Fox, what he thought [illegible] the matter with a certain woman whose case he had just been working up. The answer was, "Well, doctor, it looks to me as if she were just a plain damn fool!" The chief was so entirely satisfied with this diagnosis that thereafter, in that hospital, the particular syndrome was known as Fox's disease.

Another point that has been impressed on me time and again in the last few years is that commonly the skin tests not only fail to help the physician in his search for offending foods, but sometimes the [illegible] of a few positive results is actually a misfortune because both the patient and his physician put such a [illegible] faith in them. In many cases it is almost impossible to get the patient to touch the [illegible] foods again. I have spent hours trying to get these people [illegible] that the reaction of the skin [illegible] a trustworthy test. In [illegible] experiment of eating the suspected food to see if this makes the symptoms [illegible] the food to see if this brings relief. [illegible] canned pears? Because the skin reacted to it. Sometimes when the tests are repeated the skin is found to react to a different set of foods.

The difficulty is that we human beings are all a bit lazy [illegible] thinking and reasoning, and hence wherever possible we cling to a laboratory diagnosis which we hope will save us from having to work one out for ourselves.

SUMMARY AND CONCLUSIONS

To sum up, then, although there are more disappointments than miracles in the search for and the cure of severe manifestations of food sensitiveness, the miracles are so gratifying when they come that, each time, the clinician will resolve to spend more time looking for them. The field is still much neglected;

more diets must be fitted and fewer handed out ready made.

A good history will often show that the diet is probably not the cause for the patient's discomfort. Patients must not be left too long on narrow elimination diets; such diets are for testing and not for treatment.

Some cases of diarrhea and pseudo-ulcer are due to the milk that is taken by way of treatment, and not infrequently certain foods irritate or greatly depress the brain. Somnolence after meals can be due to a particular food, and canker sores in the mouth can be produced by food.

Efforts to use an elimination diet are often instructive in showing the physician that he is dealing with an unreasonable, overly fussy, querulous, or psychopathic person.

Food sensitiveness is not necessarily allergic or due to protein. Perhaps partly for this reason, skin tests are of little help in finding the foods that cause indigestion.

DISCUSSION

DR. ARTHUR F. COCA (Pearl River, New York): Food sensitivity is limited to the group of familial or atopic allergy in which are associated hay fever, asthma, the urticaria due to foods, atopic dermatitis, gastro-intestinal allergy, migraine and others.

In the typical case (such as hay fever) antibodies—those peculiar atopic antibodies of the human being—are regularly demonstrable in the blood and indirectly through the positive skin test. The positive skin test appears only when these antibodies are present in the blood. They are often entirely absent, for some reason that we do not understand; in such cases the skin test results negatively.

Food sensitivity can be at the bottom of any of these many clinical varieties. Some of them are associated with a positive skin reactivity and others not. If the clinical form of the food sensitivity is asthma or hay fever, or atopic dermatitis, the skin test is quite regularly positive.

I have included atopic dermatitis (neurodermite) among the clinical varieties of food sensitivity in which the skin test is frequently positive. This statement must be considerably qualified by the further remark that the direct skin reaction in this condition is almost always so weak that it cannot be used diagnostically. However, a means has been developed by Matthew Walzer in Brooklyn of magnifying this weak reaction in a way to make it a thoroughly practical and reliable specific test. This means is the indirect test, which is performed with the technic of Prausnitz and Kuestner. The test is carried out as follows:

Serum is obtained from 5 to 10 c.c. of the blood of the patient by aseptic defibrination and centrifugation. One-twentieth c.c. of the serum is injected intracutaneously in about 50 well-separated sites in the upper arm of a substitute, who must not be allergic. Three days later these injected sites can be tested with the intracutaneous method with the usual food extracts, an identical control injection being made in a normal skin site in the same skin. In comparison with the negative result of the control test, slight degrees of reaction can be recognized as diagnostic which could not be accepted as significant in the direct test in the patient's skin.

By this means, Dr. Walzer states, about 60 per cent of subjects of neurodermite can be relieved by the avoidance of the indicated foods.

Notwithstanding the valuable contribution of Dr. Walzer to the technic of skin tests in the development of his indirect test, it still remains true, as Dr. Alvarez says, that in many cases of food sensitivity, especially urticaria, allergic headache and gastro-intestinal allergy, the skin test is of very little use. It is in such skin-negative cases that the physician must fall back on the trial diet plan.

The trial diet plan can succeed only if we possess a criterion of reactions, like the wheal in the skin test, that is diagnostically significant. The criteria under the trial diet plan are, of course, the clinical symptoms of food sensitivity. Such symptoms may be immediate or delayed. Immediate symptoms are gastric pain, headache (which may occur within a hour after the ingestion of the offending food), swelling of the lips in some instances, and a peculiar sensation of the mucous membrane of the tongue, which can be very acute. Vomiting is seen in some cases. The more violent symptoms should be avoided, if possible, by administering at the first trial only a small quantity of the food to be tested, where such symptoms are feared.

I have for some time been making use of another immediate symptom which seems heretofore to have been overlooked. This is tachycardia. I do not know how often this appears. It happened to be prominent in the first four cases of food allergy that I have had occasion to study. The symptoms in all these cases were gastro-intestinal or migraine. The tachycardia can range from a rate of 80 or 90, lasting for some hours after the ingestion of the offending food. In one case that had recently suffered a coronary thrombosis, the pulse rate has risen to 160 or 180 or more within a half hour after the injection of minute quantities of the offending substance. Three of these cases could be completely relieved of their symptoms by elimination of foods through the use of the criterion of tachycardia.

Delayed symptoms are more difficult to use as criteria of reactions. These are urticaria, diarrhea, bleeding from the intestinal tract. (This latter symptom may be more frequent than is generally known because patients are not advised to examine the stool for gross evidences of bleeding). Dizziness is a delayed symptom; also extrasystole, which may be the sole symptom of food allergy in some cases. A feeling of lassitude is a distinct delayed symptom in some cases.

In the application of the trial diet principle, all plans heretofore recommended have exhibited a common error which may explain some, at least, of the many failures encountered in the use of this principle. This mistake is the illogical one of trying more than one food at a time. Different allergists recommend different combinations of food in the initial test. The successes under all these plans represent merely those lucky individuals who happened to be sensitive to relatively few foods which were not included in the first selection.

Another circumstance which has no doubt interfered with the successful application of the trial diet principle is the fact that there are allergenic foods which have not been recognized as such by even the allergists. Among these may be mentioned gelatin, which, according to the chemists, contains no native protein but which, nevertheless, can be a violent food allergen. Another allergenic food that has been largely overlooked is sugar, both from cane and from beet. There is relatively very little protein in sugar. When the protein is collected out of a solution of sugar by the process of ultrafiltration, it is found that there is something over 100 milligrams of it in 200 pounds. On the basis of the established fact that about 1 per cent of negative protein in solution will find its way through an ultrafilter when the ultrafiltration has proceeded for a period of about 48 hours, I have been able to calculate that 1/100,000 of a milligram, or possibly less, of sugar protein may cause disagreeable allergic symptoms (tachycardia, dizziness and headache) when that quantity is given daily over a period of two days.

The logical plan of applying the trial diet principle must be, first, to withhold all food until the symptoms disappear and, secondly, to administer one food at a time in ample quantity, each food being added only after the preceding

one has been given a test of not less than three or possibly two days. The period of starvation is irksome to most patients, as is also the initial period of three days when the patient is receiving only one food. With this difficulty in mind, I have hit upon the idea of providing a small basis of non-allergenic food to tide the patient over the initial period. This basis is provided by an ultrafiltered sugar solution that has been concentrated by boiling to syrup form for preservation, and ultrafiltered lemon juice, which must be preserved in sterile form after Berkefeld filtration. A patient can be kept quite satisfied for several days on nothing but this non-allergenic sugar and lemon juice, which can be taken in the form of lemonade with or without carbonated water.

DR. ANTON OELGOETZ (Columbus, Ohio): I would like to emphasize this idea of indigestion in its relation to food allergy. About six years ago we became interested in the subject of food sensitization. Perhaps you have read some of our papers. The subject finally got down to a matter of digestion.

As has been stated, Walzer has shown that whole proteins are normal constituents of normal blood. We have shown that the blood stream always contains the three pancreatic enzymes, amylase, protease and lipase in a definite concentration of two-tenths by the test which we have suggested. This concentration never varies throughout the day or night and is uninfluenced by sleep, intake of food or exercise. We have made 15 minute determinations on many, many cases, and always have found the pancreatic enzymes present in the normal concentration of two-tenths.

We, long ago, came to the conclusion that there is no specific sensitivity to foods. All proteins, all carbohydrates and all fats are enzymotically and physiologically similar, and the three pancreatic enzymes are hetero-lytic. The reason that this mistake was made, in our opinion, is because, as Dr. Alvarez has suggested, two factors are involved which have not been taken into consideration. Dr. Alvarez said that ordinarily, when at home, quite and relaxed, he does not have difficulty when he eats chicken, but when he is away from home, under unusual mental stress and strain he becomes allergic to chicken. He has suggested that indigestion might have something to do with his difficulty. We have shown on many patients that nervousness produces a temporary pancreatic hypofunction, or in some cases, a complete achylia, which is the cause of the phenomenon.

According to our conception, digestion starts in the stomach and upper bowel, where proteins are split all the way down to amino-acids. But not completely so. As Walzer has shown, much of the protein is absorbed as whole protein which is toxic to cells. It is the serum enzymes which complete digestion in the blood stream and prevent the serum proteins from reaching the cells in an unsplit state which cannot be used as food. Whole proteins are toxic, while the split products of proteins are non-toxic to cells, and it is the serum enzymes which prevent all of us from being food allergic all of the time. Food allergy results from too much food, more food than can be hydrolyzed by the available serum enzymes.

Variations in gastric secretion — hypersecretion and achylia—are commonly recognized conditions, but it is strange that we have never heard much about pancreatic hypofunction and achylia. Surely the pancreas must vary in the quantity and concentration of its secretions, just as does the stomach. We check our cases routinely for pancreatic function, by the test which we have described, and we find that pancreatic hypofunction and achylia are rather common. Since doing this test routinely, we are finding that many cases which we formerly labelled "functional" or "neurosis," or urticaria, or angio-neurotic oedema, are really food allergy, secondary to pancreatic dysfunction.

I wish to emphasize that there are two types of allergy caused by two different underlying mechanisms. One type is a true chemical irritation. The action of poison ivy on the skin, for example. The underlying mechanism of food allergy however, is different; it is a true indigestion, which results when more food is taken than can be split by the available pancreatic secretion. This mechanism is secondary to pancreatic hypofunction or achylia.

DR. IRVING GRAY (Brooklyn, New York): Dr. Alvarez has called attention to a subject that is attracting a great deal of interest. The mechanism responsible for "Specific Food Sensitiveness" is not clearly understood. We may postulate that there is either a direct action of the specific offending food in its unaltered state upon the mucous membrane of the gastro-intestinal tract or that the offending substance is absorbed into the circulation and then acts upon the mucous membrane of the intestinal tract. It is probable that both factors come into play: 1—a direct action by the food on the mucous membrane and 2—a systemic factor.

The cramps and diarrhea that occur immediately after the intake of a specific food to which the individual is sensitive, suggests the absorption of some product possibly in an unaltered state high in the digestive tract and an effect upon the small bowel and colon by way of the circulation.

Perhaps the absorption of an unaltered protein directly into the circulation may be responsible for many of the symptoms associated with, "Specific Food Sensitiveness." That protein in an unaltered state is absorbed from the gastro-intestinal tract has been proven by Dr. Matthew Walzer. During the past three years I have been associated with Dr. M. Walzer in studies on the absorption of unaltered protein in humans who have disease of the gastro-intestinal tract. Last year our paper was read by title before this Association. In that publication we called attention to the fact that the rapidity of absorption of unaltered protein is related to gastric acidity. The rate of absorption was shortened in patient's with decreased gastric acidity and prolonged in those with hyperacidity.

Three days ago we presented another paper on this subject before the Society for the Study of Asthma and Allied Conditions. We presented results on a group of patients in whom the protein meal was administered into the duodenum via the duodenal tube. Comparative studies showed the rate of absorption of unaltered protein to be somewhat faster when the test meal was administered intra-duodenally than when the food was taken by mouth. We were again impressed by the evidence which indicated that absorption following the duodenal test meal was prolonged in those with gastric hyperacidity and accelerated in patients with hypoacidity. In a future publication we will present our findings of the absorption of unaltered protein from the rectum.

The technique for studying the absorption of unaltered protein is an immunologic one and is the same as that which was used by Dr. Walzer in previous studies with egg and fish antigens. Peanut was the protein chosen for investigation in the present series because a serum particularly suitable for the study of this antigen was available at the time.

Peanut was excluded from the diet of the subject for 24 hours preceding the experiment. The subject was then passively and locally sensitized on the forearm by the intracutaneous injections of .05 c.c. of a 1-10 dilution of "C" serum. This serum had been obtained from a patient who was extremely sensitive to peanut and who manifested a marked reaction to intracutaneous tests with this antigen in very high dilution. One or two days later, the subject reported early in the morning without breakfast for the peanut test meal. The latter consisted of a "milk" made by dissolving 10 gms. of raw ground peanuts in 30 c.c. of water to which was added 1 gms. of sugar and .05 c.c. of oil of cloves. Shortly after the ingestion of this meal, a

reaction developed at the sensitized site, which usually consisted of pruritis, erythema and wheal formation. The onset of this reaction marked the entrance of the undigested peanut protein into the circulation.

The absorption time of each subject was measured from the time the test meal was taken to the first objective symptom noted at the sensitized site, namely erythema or wheal.

Sufficient proof has been accumulated to show that unaltered protein is absorbed directly into the circulation and that the rate of absorption is influenced by the degree of gastric acidity. Absorption time is shortened in individuals with decreased acidity and prolonged in individuals with hyperacidity.

Coca and Grove have pointed out that "the atopic reagin is specific. In the blood of individuals sensitive to more than one substance, more than one reagin can be demonstrated." Evidence that the protein responsible for the local reaction is in an undigested state has been shown recently by Alexander, in animal experiments.

DR. LEON BLOCH (Chicago, Illinois): I would like to ask Dr. Alvarez what experience he has had with this thrombocytopenia and allergy?

DR. WALTER ALVAREZ (closing the discussion): The ideal elimination diet, of course, would be no diet at all, or a complete fast, but most patients are a bit too fussy for this, and so we compromise. Occasionally when I want to learn quickly whether or not some symptom such as daily headache is due to the eating of food I ask the patient to eat nothing but maple sugar. When after several days of this, symptoms persist they are not likely to be due to food. In years I have met only a few people who seemed to be sensitive to cane or beet sugar. Theoretically a person sensitive to cane sugar should not be sensitive to beet sugar, but whether this is true or not I cannot say.

Dr. Aaron asked me why I use lamb, rice, butter, sugar and canned pears. I do because these foods rarely seem to bother people, and with them I can supply protein, carbohydrate, fat and dessert. Lamb seems to bother people much less frequently than beef does, and rice rarely offends.

A person would probably have to be very sensitive to milk in order to get discomfort out of a well-washed butter. Few people seem to be sensitive to pears.

Theoretically arrowroot, tapioca, and other such starches of foreign origin would be good foods for inclusion in an elimination diet because they are used only in small amounts. Unfortunately, cooks are not accustomed to preparing these substances without adding milk and egg.

I know of Vaughan's work and have been interested in it, but I haven't experimented with it. It seems to me that we can save time and expense by testing each food by its reactions on the patients' comfort and not on his white count.

I doubt very much if many of the disturbances due to food are allergic in nature or caused by protein. I feel sure that there are other substances in foods that can cause trouble. It may well be as someone suggested that some of our troubles are due to a stoppage of pancretaic digestion. Such stoppage may produce hunger pain in some persons by eliminating one of the fluids that dilutes and neutralizes the gastric acid.

I have been told by some physiologists that the pancreas is very sensitive to inhibiting influences arriving by way of the nervous system. Others deny this. I agree with Dr. Oelgoetz that we ought to make a careful study of pancreatic achylia and the causes which produce it.

Certain Newer Methods of Treating Peptic Ulcer*

By

ANDREW B. RIVERS, M.D.†

ROCHESTER, MINNESOTA

NO definite standardization of medical regimens for the treatment of all peptic ulcers has been accomplished, nor do I expect that this will ever happen. It is questionable whether peptic ulcer should be considered a specific single disease entity. It is a disturbance with such varied histopathologic features and the factors important in its etiology are so variable that the treatment of the condition will remain a problem specific in individual cases. Yet the search for the Golden Fleece, the panacea, goes on, and with every change of season there appears some new and ingenious therapeutic masterpiece. Patient's hopes are raised only to be crushed by subsequently recurring episodes of distress. From time to time therapeutic measures of a more promising nature are developed. It is my purpose in this paper to consider some of these and to attempt an appraisal of the principles on which their alleged usefulness depends.

*Delivered at the Thirty-ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936.

†Division of Medicine, The Mayo Clinic.

Approved by the Publication Committee.

CERTAIN FACTORS OF KNOWN IMPORTANCE IN THE GENESIS OF PEPTIC ULCER

To treat peptic ulcer symptomatically is to apply tape to a leaking pipe; nothing lasting is accomplished by such a procedure. There must be a determinate plan in treatment which seeks to control or eradicate forces of recognized importance in the causation of this disease. Before proceeding to the discussion of what might constitute a reasonable yardstick with which to measure the methods of ulcer therapy considered in this paper, it would be well to scrutinize some of the experimental lessons which physiologists are able to teach with regard to the disease. Correlating these with clinical experience makes it obvious that certain principles pertaining to this problem must be recognized and contended with if any success in treating peptic ulcer is to be expected.

Gastric acidity and tissue defense. Although there are many inter-related factors which are important in the causation of ulcer, these ultimately resolve themselves around two: the one inherent in the ulcerating

potentiality of acid-pepsin, the other maintained in the defenses which the tissues possess and by which they protect themselves against the eroding action of the gastric chyme. It would seem that the alternating activity and quiescence which are so characteristic of such lesions would be evidence of two forces, the one of aggression and the other of defense, and that the outcome would depend on which factor was dominant at any particular stage of the life cycle of peptic ulcer.

Physiologists have demonstrated that the component fraction of gastric juice which can produce erosion is inherent in the acid-pepsin factor. The eroding tendency seems to fluctuate, not with variations in peptic concentration, but with the concentration of hydrochloric acid. Tissues laved in pure undiluted gastric juice are very likely to undergo erosion. Tissues which in their normal physiologic existence are regularly exposed to the acid chyme, however, possess definitely more resistance to the eroding action of acid than those which are not normally exposed to gastric chyme. Gastro-duodenal mucosa is more resistant to the processes of erosion than are other tissues. It has been suggested that the first factor of defense lies in the living gastro-duodenal cells themselves.

The neutralizing effect of alkaline blood in mucosal capillaries, the protective action of gastric mucus, and the presence of alleged antipepsin in its gastric mucosa have been considered as a possible explanation of the obvious mechanisms of defense in gastric tissues. An important factor responsible for the increased resistance of the duodenal cells to ulceration is inherent in the glands of Brunner, which under the necessity of neutralizing acid chyme suffuse the duodenal membranes with a profuse amount of an alkaline mucoid secretion. Nor must the protective importance of the secretions which are poured into the duodenum by organs which are extrinsic to the gastro-intestinal tract be underestimated. Bile and pancreatic juice have been shown to be of definite importance in protecting duodenal tissues against erosion by acid chyme. Furthermore, it is suggested that it may be one of the functions of certain hormones elaborated by the wall of the upper portion of the intestinal tract, among which is enterogastrone, to retard the gastric secretory rate. Although the duodenum has a remarkable reserve function in its capacity to neutralize and to buffer acid, it has been shown by Mann and Bollman (1), Baker (2), Florey and Harding (3) that it will break down under the necessity of neutralizing without interruption of the acid chyme. Ordinarily, in the daily physiologic fluctuation in the curves of gastric acidity there are alternate periods of rapidity and retardation in the secretory rate, thus giving the cells bathed in this chemical atmosphere "breathing spells" during which the forces of defense can be adequately reëstablished. Physiologists have shown that the continuous feeding of hydrochloric acid is likely to cause the eventual break-down of cells called on to resist the digestive action of the gastric chyme.

Corollaries for these experimental observations are obtainable in clinical experiences with certain patients harboring peptic ulcer, particularly those found to have duodenal or jejunal ulcers. The gastric secretory rates of such patients are usually accentuated, particularly during or preceding periods when there is definite activity of the ulcer. Following ingestion of such stimulating substances as histamine, patients with peptic ulcer frequently continue to secrete a highly concentrated acid for considerable periods after a drop in acidity would ordinarily have been expected. If such cellular behavior actually obtains in response to other stimuli, it would be obvious that the gastro-duodenal defense mechanisms of patients with peptic ulcer might be forced to exert themselves accordingly. It seems logical that the activity of these mechanisms of defense would have to fluctuate in proportion to changes in the potency of the mechanisms of aggression.

Unquestionably one of the important causes of cell dissolution which results in peptic ulcer lies in the exhaustion of the defensive powers of the cells: they may have used up their own as well as all available reserve sources of defense. The forces of erosion, through the utilization of an inherent chemical factor alone, can break down normally resisting tissues and cause ulceration. There is no reason to assume that human tissues behave differently.

Although local chemical and mechanical reactions in the stomach and doudenum are probably of the greatest intrinsic importance in the formation of peptic ulcer, ulceration can in all probability be influenced by other factors, of which several seem of pertinent importance:

The first of these factors is diminished resistance of tissue to acid aggression. If normal tissues can disintegrate under the prolonged bombarding influence of highly aggressive acid chyme, it is not difficult to assume increased liability to ulceration in tissues deficient in the mechanism of defense. This may be attributable to some congenital inadequacy in the tissues themselves as suggested by Smithies (4) and others, or to some acquired disease invading the tissues, such as inflammation or infection.

Next in importance are systemic-neurogenic factors. Certain individuals have an increased tendency to the formation and reformation of peptic ulcers. Efforts to catalogue and to categorize these systemic-neurogenic factors into definite groups by various physical measurements have not been successful because the distinguishing features seem more psychophysiologic than physical and anatomic. A striking uniformity of temperament is noted in certain groups of patients who have peptic ulcer. They are alert, attentive, keen. They are often introspective, suspicious, sensitive and given to periods of worry and depression. The periodicity of symptoms in cases of ulcer frequently is determined by variations in the psychophysiologic influences incident to the patient's daily experiences. During periods of unusual worry and tension, symptoms are likely to originate or to be reëstablished. Marked elevation of the gastric secretory rates is often noted during periods of excitement and tension, and it may be that one of the mechanism of the formation of ulcer is related directly to gastric chemical conditions which are thus affected by disturbances in the nervous system.

Utilization in treatment of factors important in the etiology of ulcer. A survey of the factors which seem important in the causation of ulcer permits a concentration of these into three groups: (1) factors of acid aggression and tissue defense; (2) the factor of local trauma to tissue; and (3) systemic-neurogenic factors. Although peptic ulcer may result from a single cause, it is probable that the interaction of several or all of these represent the usual formula. Now one, and now

another of these factors assuming the position of greatest importance.

Physiologic, bacteriologic, and clinical observations attest the fact that peptic ulcer is merely a local manifestation of a disturbance in gastro-duodenal tissues which in turn is brought about by various systemic causes. The patient as a whole must therefore be the subject of diagnostic scrutiny and therapeutic consideration.

The forces of erosion, although perhaps using the same weapon of offense, namely, the acid chyme, are varyingly offensive and are stimulated into action by various and varying means. In addition to making efforts to control or to assuage the acid factor, it would then be evidence that a rationale for defense against peptic ulcer should recognize such variations in offense and direct treatment accordingly.

The breakdown of tissues probably results not from one but from various causes, among which several are pertinently important. There may have been a localized anomalous tissue or vascular defect, tissue resistance and hardiness may have been damaged by local injury or by the products of infections or inflammatory disease, or tissue resistance may have been diminished by debilitating systemic disturbances or exhausted by the prolonged necessity of withstanding unusually active forces of erosion.

The tendency still remains to treat the single exacerbation of ulcer as a disease in itself when, in reality, it constitutes merely a single breakdown in the life cycle of ulcer. One successful stand against the mechanisms of aggression does not as a rule end the play of contending forces. Treatment must include some consideration of ways and means to keep dormant those forces which may be so difficult to control when they are stimulated into activity.

It is obviously quite necessary to make an individual problem of each case of peptic ulcer. A *rationale* for the treatment of such lesions must include not only a single method which is applied in all cases, but it must be sufficiently flexible so that special attention is given to such factors as are found to be predominantly important in individual cases. A general plan for ulcer therapy must include provisions for: (1) the management of complications and the control of distress, (2) the planning of a regimen to promote adequate healing of the ulcer, and (3) the prevention of recurrences.

I have spent some time in considering factors of etiologic importance in this disease in order to point out the necessity of directing therapeutic attention not to one, but to many factors which may be extremely variable. Realizing my inability to judge properly the usefulness of the new methods of treatment considered in this paper, I sent a questionnaire to a group of physicians who are particularly interested in the problem of ulcer therapy. I was interested to find that only 9 per cent were favorably impressed by methods other than those which might be considered the old approved methods of ulcer therapy.

A CONSIDERATION OF AGENTS USED IN THE TREATMENT OF PEPTIC ULCER

Vaccines. At the clinic we have employed many variations of vaccines as supplements or substitutes for other methods of ulcer therapy. Stock vaccines made from organisms known to produce ulcer in experimental studies on animals have been tried. In other instances autogenous vaccines were used. Although in a few instances we believe that the healing process was accelerated by the use of such substances we have never been convinced that vaccine therapy had an important place in the treatment of peptic ulcer. Only 2 per cent of physicians who have a large experience in the treatment of ulcer attributed beneficial effects to this type of therapy.

Nonspecific proteins. Various nonspecific proteins have been given parenterally in the treatment of peptic ulcer. These have been prepared from organisms such as staphylococci, Bacillus prodigiosus and gonococci and from crystallized plant, milk and various other proteins. It was hoped by these methods to produce local conditions about the ulcer and some mild general febrile reaction favorable to healing of the lesion. We have tried several types of foreign proteins in treating ulcer, but with no encouraging result. At times, particularly in cases in which complications are present, the administration of such foreign proteins is dangerous. It is usually not a difficult procedure to initiate the healing of peptic ulcers, and this seems to be the main reason for using such substances. Thirty-five per cent of specialists in gastro-enterology to whom questionnaires were sent had tried one or more of these foreign proteins in the treatment of ulcer. Only 8 per cent were of the opinion that they had obtained some beneficial results therefrom.

Metaphen. Metaphen is an organic mercurial compound originally elaborated by Raiziss and Severac (5), after an extensive study of the chemical compounds involving the nitro-benzine-mercury complex. Chemically it is 4-nitro-5-hydroxy-mercuri-orthocresol. Trippe (6), on the presumption that infection played an important rôle in the production of gastro-intestinal ulcer, felt that the use of strong bactericidal agent, which at the same time was noninjurious to tissues, should exercise a healing effect on ulcers. He believed that its use was also indicated because its action is not greatly diminished in the presence of proteins. Furthermore it was assumed that the toxicity of this substance was very low. A 1 to 500 aqueous solution of metaphen is used.

Although I am not at all convinced of the usefulness of this substance in cases of duodenal ulcer, I have had some encouraging results from its use in cases of duodenitis, erosive gastritis or in those of shallow gastric ulcer. It seems unquestionably true that in certain cases in which there are gastric, or perhaps even duodenal, lesions, local disturbances in tissue are of paramount etiologic importance. In such instances it is suggested that metaphen may exert a beneficial effect when administered in conjunction with other approved methods of treatment. Only 20 per cent of the physicians whose opinions I sought relative to the usefulness of this substance had tried it; 4 per cent were of the opinion that it had some value in the treatment of ulcer.

Mucin: Mucin is a substance prepared from the mucosa of hogs' stomachs. According to Fogeslon (7) mucin is useful in the treatment of peptic ulcer because it coats the ulcer and protects it against the proteolytic action of the gastric secretion; through its high combining power with free acid, mucin unites with enough hydrochloric acid not only to neutralize the corrosive action of the gastric juice, but also to

prolong the rate of dialysis of pepsin through the protective layers of mucin.

Theoretically the use of gastric mucin in the treatment of peptic ulcer seems a reasonable procedure. Mucin may well have a coating effect on the ulcer, and it is one of the natural gastric diluents. Both of these factors should contribute to the healing of peptic ulcer. It is difficult, however, to insure the maintenance of adequate amounts of mucin in the gastric content. In order to accomplish this, mucin would have to be fed at very frequent intervals, and this is not entirely practical.

I do not believe that mucin therapy regularly produces more favorable responses than do the customary methods of treatment. There are some patients, however, who in our experience at the clinic were benefited by the use of mucin when other methods of treatment failed. Various vegetable mucilages have also been added to the armamentariums of those treating peptic ulcer. Although these are less distasteful and less expensive than gastric mucin, they are less effective. Forty-four per cent of physicians to whom questionnaires were sent had tried either mucin or the vegetable mucilages. Seventeen per cent were favorably impressed with mucin and 11 per cent thought they noted some improvement following the use of the vegetable mucilages.

Synodal. Synodal is a foreign protein to which has been added lipoids and, finally, emetine. It is given parenterally. Pitkin (8), and later Cunha (9), were greatly encouraged by the results from its use. Cunha attributed the beneficial effects of this form of treatment to several reactions: "The included lipoprotein allegedly decreases gastric peristalsis, arrests pylorospasm, and produces hyperemia of the gastric mucosa, thus promoting healing." Cunha was of the opinion that emetine, by relaxing smooth muscle, reduces pyloric spasm, and he also thought that emetine might act favorably because of its "antibacterial properties." He suggested that the latter characteristic probably was the result of a change in the acid-base equalibrium of the tissues, thus inhibiting bacterial growth.

These are desirable accomplishments indeed, but we at the clinic do not believe that experience actually corroborated the hopes and expectations of those who originally were so enthusiastic about the usefulness of this substance. Of the physicians to whom I sent questionnaires only thirty-five had tried synodal; twenty of these were definitely opposed to its use and eight believed that it might have some use in treating ulcer.

"Larostidin." Larostidin is the trade name for histidine-monohydrochloride. By some method of reasoning, not entirely clear to me, Weiss and Aron (10) considered the absence of the essential amino acids in metabolism as the important factor in the causation of ulcer. Volini and McLaughlin (11) subscribed to the opinion that histidine promotes, restores and maintains the epithelial integrity of the gastric and duodenal mucosa. They felt that under certain conditions histidine, an essential amino acid, is not synthesized in the human body and thus were of the opinion that there is produced a metabolic defect which they hoped could be restored by parenteral injection of larostidin. They further suggested that histidine may stimulate the production of histaminase, which they hoped would inactivate histamine. Additionally they believed that this type of therapy reduces gastric acidity, gastric secretion and, possibly, peptic activity. A diminution in gastric motility has also been noted in certain cases.

All of these accomplishments would be desirable indeed, and it must be admitted that if such results could consistently be obtained when this treatment was utilized, larostidin would be a most valuable adjunct to ulcer therapy. I, however, have been unable to corroborate the impression that histidine consistently reduces gastric acidity; as a matter of fact I have noted the opposite effect in studies by means of the double histamine test.

My experience with larostidin, which includes cases in which the patients have been treated by me and a large number in which the course of treatment was given by others, has not been satisfactory as far as permanent results are concerned. In some instances there has been some symptomatic improvement, and distress has occasionally been promptly relieved following injections of histadine; experimental work now being carried on at the clinic with larostidin, however, is not producing the encouraging results noted by some investigators. More than 50 per cent of physicians whose opinion I sought in the evaluation of the usefulness of these substances had used larostidin in the treatment of ulcer; only 11 per cent were encouraged to continue its use.

Duodenal and jejunal feedings. It has been suggested that the most satisfactory manner of treating peptic ulcer is to pass a small tube into the duodenum or jejunum so that feeding can be accomplished beyond the area of ulceration. Thus it is assumed that the ulcer will heal more readily. It has been particularly advised by some investigators in cases in which it is difficult to control night distress. Continuous drip feeding is suggested by some of the advocates of this method of therapy.

Clinically, jejunal feeding has been shown to be of definite value in the treatment of certain intractable types of peptic ulcer. Many diets have been recommended, and even though they contain food substances which are stimulating, they seem to help in the healing of these ulcers. Appell (12), in some recent investigative work in which he made duodenal, jejunal, and gastric fistulas, showed that most foods when placed in the jejunum will cause an increase of the secretory rate of the stomach. Cream and casein consistently stimulated gastric acidity and secretion to a high degree. Apparently, therefore, healing is not dependent primarily on the secretory activity of the stomach in these cases but rather on its retarded motor activity. Unquestionably jejunal feeding allows the stomach considerable rest and it must be this factor which hastens the healing of ulcer in these instances. Appell noted that the pH of the duodenum is higher on jejunal feeding than with any other types of feeding. This increased alkalinity of the duodenal content in spite of increased acidity in the stomach may be a factor in the good results obtained in cases of duodenal ulcer following jejunal feedings. Although this method of therapy may be advisable in certain instances, it is obviously impractical and unnecessary in the average case of uncomplicated peptic ulcer.

Forty-nine per cent of physicians to whom questionnaires regarding ulcer therapy were sent had used duodenal or jejunal feedings in the treatment of peptic ulcer. Twenty-five per cent of these were of the opinion

that this method of treatment had some usefulness in treatment.

COMMENT

In discussing the treatment of peptic ulcer I suggested that it could be divided into three stages; the first of which was the control of distress and the management of complications. During the acute stage of such complications of ulcer it would be dangerous to use vaccines, foreign proteins, synodal or larostidin. Metaphen would certainly be useless and the passing of duodenal tubes might actually cause harm.

The second stage of treatment is the insurance of adequate healing of the ulcer and the application of several physiologic principles is important at this stage. Provision must be made to control the forces of erosion, the healing process being facilitated if gastric acidity, and perhaps peptic activity, are diminished. This is not accomplished regularly by any of the methods of therapy considered in this paper. Gastric motor activity should be protected; duodenal or jejunal feeding aid this, but I can see no reason why this should be favorably influenced by the parenteral methods of treatment or by administration of metaphen. Tissue defenses should be assisted. It is possible that these substances may have some value in fulfilling this therapeutic requirement. Conclusive proof of this, however, is as yet not available.

The third stage of treatment is prevention of recurrences. This is one of the most important tasks of the physician who conscientiously seeks to help the patient with peptic ulcer. Sane methods of living, adequate rest, supplementary feedings, avoidance of infection and nonstimulating diets, are the reasonable ways of accomplishing this. There is no place in this stage of therapy for the newer methods of treatment considered in this paper.

Metaphen may at times be useful as an adjuvant to other treatment of the infected stomach with erosions or ulcers. Mucin therapy is reasonable and may at times help when other methods of treatment fail. Duodenal or jejunal alimentation is occasionally successfully employed to control the symptoms of intractable ulcer. It seems especially useful in the control of night distress.

In the final analysis the parenteral methods of treatment seem to possess no definite claim to merit except in so far as they may initiate or accelerate the healing process of tissue repair. It is doubtful whether this occurs regularly with greater facility than can be accomplished by the older approved methods of ulcer therapy.

It is not my purpose to condemn these various methods of treatment. It is consoling still to have several things to try when the patient is not doing well on pet methods of treatment. In such an instance, however, it is better to concentrate on the method under trial, to work a little more extensively to get the patient to coöperate in treatment, rather than jump from one method to another, which is expensive, destroys the patient's confidence, and in the end usually results in failure.

DISCUSSION

DR. WALTER L. PALMER (Chicago): I think we owe a real debt of gratitude to Dr. Rivers for this very splendid and lucid exposition of the subject. There is in it nothing with which I care to take exception and therefore I shall not devote any further time to a discussion of the points mentioned by him, but will rather devote it to a consideration of why it is that we have so many methods of treatment for ulcer.

Now, of course, it is obvious that one of the reasons is that we have no method of treatment which is entirely satisfactory. If there were a specific one such as quinine is in malaria, for instance, there would be no argument as to which is the best method of treatment.

Another reason, it seems to me, for the numerous methods of treatment is that the drug houses annually spend large sums of money in order to induce the medical profession to feel that this drug, or that drug, when given intravenously, or some other way, is the finest method of treatment. So, we are all deluged by the detail men who come out and tell us amazing stories. I think we must admit that we physicians as a whole are very gullible men.

Another difficulty is that we have no control group. So far as I know, no one has ever treated a large series of cases in a satisfactory control manner. We know, as Dr. Crohn and others have pointed out, something about the life story of ulcer. We know that there are these spontaneous periods of remission and of exacerbation. Dr. Rivers has adequately considered some of the reasons for the periodicity, but still there is much about it which we do not understand.

A very important fact which is usually overlooked in evaluating results is the role of psychotherapy. We all appreciate the importance of psychotherapy when we are treating the patient, but, in how many instances is it adequately evaluated in a study of results? I might cite, for instance, a patient with a recurrent gastrojejunal ulcer who was unable to tolerate alkalies because of impaired renal function and who did not obtain relief from pain from the various treatments tried. He was told by a wealthy friend that he would be glad to finance a vacation to Europe. On the fourth day out on the boat en route to Europe the ulcer pain disappeared. The patient spent three months touring the continent, eating and drinking everything, attending all of the night clubs in Paris and experienced no more ulcer pain until a month after his return. I am unable to explain this on any other basis than some kind of a psychosomatic reaction. It constitutes further evidence that psychotherapy is extremely important in the evaluation of the results of any type of treatment.

I was reminded yesterday of an article by Maynard written several years ago. Maynard made a pathologic study of the gall bladder removed by the surgeons at operation and then attempted to correlate the changes present with the symptomatic relief afforded by the operation as subsequently reported by the patient. He found that when

stones were present in the gall bladder 84% of the patients reported symptomatic improvement; that when chronic cholecystitis only was present, 65% reported improvement; and that when the removed gall bladder was found pathologically to be normal, 70% of the patients nevertheless reported the operation as clinically successful. We must remember that a major operation such as a laparotomy is a major psychotherapeutic procedure.

Aymen, in Boston, a few years ago reported a study on the effect of psychotherapy in hypertension. He observed the effect of giving ten drops of dilute hydrochloric acid three times per day "seriously and enthusiastically." Dilute hydrochloric acid was selected as the drug to be used because scarcely anyone would have the audacity to say that it could be of therapeutic benefit in any manner except pychotherapeutically. Aymen reported symptomatic improvement in 82% of the cases.

Now with regard to practical methods of treatment for ulcer, I quite agree with Dr. Rivers that the old standard method, particularly the one devised by Dr. Sippy, is the best we have. It is not, as we all know, nearly as successful as it should be, or as we would like to have it. The great difficulty, as has been pointed out by many, including Dr. Sippy himself, is the high night secretion and our difficulty in accomplishing its neutralization. We have studied, as have Winkelstein and others, the height of this secretion during the night in patients with and without ulcer and have found it to be much higher in the ulcer group than in the normal in terms both of free acidity and volume of secretion.

We have tried the Winkelstein drip. I must say it does a better job of neutralizing the free acid throughout the day and night than any other method of treatment which we have employed, except partial gastrectomy. The difficulty of course, is that one cannot keep it up forever. We have continued it for two or three months at a time. We have induced healing of the ulcer, but as Dr. Rivers has pointed out the lesion returns. Nevertheless the method is at times of great value.

Atropin, we feel, has a definite role in therapy because it does decrease the volume of secretion, but, of course, it is not possible clinically to give enough of the drug to completely inhibit gastric secretion.

In conclusion, I take pleasure again in thanking Dr. Rivers.

DR. SANDWEISS (Detroit, Michigan): Dr. Rivers has given us a comprehensive and timely paper on some of the newer methods in the treatment of peptic ulcer. Without a doubt his work will help us in evaluating more accurately the results and indications of some of these therapeutic agents.

About two years ago Dr. S. G. Meyers and I reported our experiences in the treatment of peptic ulcer with a stock respiratory vaccine. We pointed out that although a goodly number of these patients became symptom-free shortly after vaccine therapy was begun, many returned with relapses of ulcer symptoms within one year. Ninety-seven per cent of the patients who became symptom-free developed ulcer relapses within two years.

In my report on forty patients with chronic peptic ulcer treated with histidine (Larostidin), recently published in the Journal, I pointed out that 55% became symptom-free. Of the patients who became symptom-free, 85% returned with relapses of ulcer symptoms within 6 months. This speaks unfavorably for lasting benefits to be obtained from the use of histidine in ulcer therapy.

Dr. Palmer stated that he has failed to find reports on the parenteral treatment of peptic ulcer which included comparative results with control series. I should like to call his attention to the fact that in my report on histidine, previously mentioned, I included not only a control series treated with the standard diet-alkali regime, but also a control series treated with injections of distilled water. I found that the results in these three series of patients were practically the same. I should like particularly to call your attention to the fact that injections with distilled water produced the same immediate results as did injections of histidine (Larostidin).

With reference to the experimental work on histidine mentioned by Dr. Rivers, I should like to add that Drs. Saltstein, Glazer and I have been unable to corroborate the work of Weiss and Aron. In our hands, thus far, peptic ulcers regularly followed the Mann-Williamson operation in dogs even though they had received daily injections of histidine, starting immediately after the operation. I hope to present a preliminary report of this experimental work at the forthcoming meeting of the American Medical Association, Kansas City, showing photographs and photomicrographs of ulcers produced in Mann-Williamson dogs following histidine injections.

I have used four different parenteral methods of treatment in 118 patients with peptic ulcer during 176 ulcer attacks. Approximately 50% of these patients became symptom-free. It is my impression that the psychic factor plays an important role. The physician, in order to justify ten or fifteen or twenty-five injections must of necessity also inject into the patient's mind certain elements favorable to the treatment. He must tell the patient that the parenteral method of treatment is a new treatment, that eminent physicians the world over have reported successful results with its use, that the patient may be able to follow a more balanced diet, etc., etc. These encouraging statements to my mind play a great part in the results obtained.

Here I would like to stress the following facts: Some patients do not respond to any form of medical treatment, whether it be diet and alkalis, mucin, vaccine, Larostidin, Synodal or what not. But, when the psychic problems of these patients are relieved, whether they be environmental difficulties or emotional conflicts, at times an almost miraculous response occurs with or without other therapy. Until more is known about the etiology of peptic ulcer, not only must one manage the ulcer but above all, manage the patient in so far as tensional states are concerned.

DR. ASHER WINKELSTEIN (New York City): Dr. Rivers is to be congratulated on his very able presentation.

The ultimate cause of ulcer is unknown. Three theories are most tenable (1) psychogenic (2) ductless glandular, and (3) inflammatory (infectious?). There is no absolute proof for any of these theories as to the cause of ulcer, but the mechanism by which ulcer is produced seems fairly well-established experimentally and even clinically. It is due either to crises or prolonged hypersecretion of hydrochloric acid, probably vagal in origin, or it is due to the normal or increased acid acting on the tissues rendered vulnerable by an unknown cause. While we cannot attack this unknown factor because we do not know its nature we can attack the known mechanism. The problem of medical therapy in peptic ulcer is to produce that chronic achlorhydria which, as Dr. Alvarez said yesterday, we love to see in our ulcer patients. To date, no medical therapy accomplishes that end. The chief objection to the usual forms of medical therapy is that during the night the stomach is filled with large amounts of concentrated free hydrochloric acid.

Several years ago before this Association I presented a method of controlling the free acid day and night, viz; the continuous intragastric milk drip (alkali is not necessary).

I want to correct Dr. Rivers and many others who have the mistaken idea that this is an intraduodenal or an intrajejunal feeding. It should be emphasized that this is an intragastric milk drip, and this is highly important because the purpose of the treatment is to neutralize the acid in the stomach continuously as it is secreted. If one aspirates samples day or night from these patients, in practi-

cally all the cases there is no free hydrochloric acid and a low total acidity.

Since presenting the method, I have treated over 150 cases and am familiar with the results in another 200 cases so treated by others. The important points about the treatment are as follows: (1) often the patient need only be taught for a few days how to use the milk drip and then be advised to continue it for long periods of time at night at home, (2) it does produce that achlorhydria that we love to see, (3) it is not a heroic method; it is essentially a practical method, particularly for the night, (4) it is successful very frequently when other methods fail.

If it does fail to relieve the patient's symptoms we are probably dealing either with an error in diagnosis, or, a complicated ulcer requiring surgical therapy, or, a profound psychic factor.

I wish to correct one other misconception. One should not speak of a "cure" in chronic ulcer patients: The only cure that I know of for peptic ulcer is partial gastrectomy followed by permanent achlorhydria. Other methods of treatment relieve the patient temporarily and then, sooner or later, the disease recurs.

DR. ALBERT F. R. ANDRESEN (Brooklyn, New York): I consider this paper of the greatest importance.

Such a discussion of the merits of the many newer treatments for peptic ulcer is particularly timely. It is unusual today to see patients with gastro-intestinal symptoms, whether due to ulcer or not, who have not received at least a few of these newer treatments. I have recently seen a patient who had been taking mucin for two years and had had 75 mucin injections, who had no ulcer, but a simple case of sensitivity to milk.

It is only by a consideration of etiologic, pathologic and physiologic factors that we are going to get anywhere in our treatment of ulcer patients, and papers of the type we have listened to this afternoon will do much to clarify the situation. However, one piece of research work, of the utmost importance, has not been given due consideration. This is the work of Lewis Gregory Cole, the successive steps of which have been presented before us in the past four or five years and will be discussed again later today. It was suggested today, and very wisely, that not enough of the researches with newer treatments had been checked by controls. Cole has demonstrated that gastric ulcers, without any specific treatment (or in spite of it) will heal, spontaneously and rapidly. We have demonstrated the same fact in our patients. This rapid healing goes on in spite of the bathing of the ulcer by a hyperacid medium. In older experiments peptic ulcers produced artifically in animals were found to heal so rapidly that they were spoken of as being unlike human "chronic" ulcers, but Cole's work has shown that this makes them like the human ulcers. As a matter of fact we must realize that the rapid healing of gastric ulcer has long been made use of in the differential diagnosis between ulcer and cancer, in that an ulcer which fails to show a disappearance of the crater or a marked diminution in its size is considered malignant.

Cole's demonstration of complete and spontaneous healing of ulcers and the radiographic demonstration that each successive attack of ulcer symptoms represents the occurrence of a new ulcer is capable of demonstration by anyone who, instead of assuming that recurrences are due to the previous ulcer, will again study his patient radiographically. I have seen successive attacks in a patient, due to a lesser curvature ulcer at one time, a duodenal ulcer at another, and a prepyloric ulcer at another, with disappearance of evidences of ulcer at the previous sites or with evidences of slight deformities.

A simple, uncomplicated ulcer is acute, heals spontaneously and requires no treatment. In treating the patient, our main objective is to relieve his symptoms. This is done by frequent feedings, which relieve the hunger contractions causing the pain. The type of feeding is unimportant, except that bland food would seem most logical. Hydrochloric acid does not cause symptoms or prevent healing—I have seen patients do well with the administration of extra hydrochloric acid. The only ulcers requiring specific treatment are complicated ulcers—those having perforated or nearly perforated, with subsequent deformities due to cicatrices, exudates and adhesions, usually requiring surgical intervention, those having bled excessively, necessitating treatment for hemorrhage, and those which were due primarily to malignancy, necessitating early surgery.

The real problem in the treatment of ulcer, as I see it today, is the prevention of the recurrent ulcers—a subject not discussed today.

DR. ANDREW B. RIVERS (Rochester, Minn., closing the discussion): Dr. Sandweiss suggested that in certain instances the use of "larostidin" in the treatment of peptic ulcer was followed by definite improvement. There is evidence to suggest that larostidin might act as a foreign protein and in this way produce beneficial results in some instances where other methods failed to produce prompt results. In our experience, however, larostidin has not given enough promise of permanent benefits to continue its use. In certain instances it might be tried when other, more easily applied methods of therapy fail.

Dr. Winkelstein is to be congratulated upon the efficacy of his gastric drip method in controlling the symptoms of ulcer. In my summary I was not referring to the method of treatment advised by him; I was discussing duodenal and jejunal feedings. Theoretically, all of these methods may have some advantage, and they can be held in reserve to be used in intractable cases which otherwise fail to respond to therapy.

There is a great deal of discussion about the cause of ulcer. An effort is made to find one cause for all ulcers. In all probability peptic ulcer represents not a single disease, but a group of diseases in which not one but a series of causes interact to produce it. Obviously no single cause and no single type of treatment will ever be discovered which will apply in all cases of peptic ulcer. Each case of peptic ulcer is a separate problem which requires individual study and individual processes of therapy.

Cystadenomata of the Pancreas
A Surgical Report*

By

R. FRANKLIN CARTER, M.D.

and

LOUIS SLATTERY, M.D., (by invitation)

NEW YORK, NEW YORK

CYSTADENOMATA of the pancreas are among the more infrequent cystic lesions of this organ. Due to the prevalence of drainage and marsupialization as a method of treatment of pancreatic cysts, there are certain instances where an accurate anatomical diagnosis cannot be made from the tissue available. In a series of 19 cases collected from the members of the Chicago Surgical Society, McWhorter found one of malignant papillary adenoma of the pancreas which was thought after examination to have arisen from a cystadenoma. In a longer series of 88 operative and 20 postmortem cases Mahorner and Mattson report two cases of cystadenoma. In view of the border line pathology of many cystadenomas the occurrence of three carcinomas in the series of McWhorter and four carcinomas in those cited by Mahorner and Mattson, the question arises as to whether some of these cases may not have had origin in relatively benign cystadenomata.

The pathology described is quite variable. The majority of the adenomatous cysts are multilocular in character, but this feature is not necessarily present. The cellular structure and microscopic pathology also varies greatly. One type shows pancreatic tissue retaining a fairly normal appearing acinar and ductile structure. The second type commonly described shows a tall columnar epithelium with basal nuclei closely resembling in cellular appearance the cystadenomas of the ovary. Both types may show a certain degree of papillary proliferation of the lining epithelium. The wall in most instances contains fibrous tissue and smooth muscle fibers. The contents of the cyst are generally mucoid in character and contain large amounts of broken down material. There may or may not be pancreatic enzymes in the fluid. Surrounding and walling off the cyst there is a dense capsule of fibrous tissue, undergoing subacute inflammation.

The variations in cellular structure presented by these cysts have led to considerable speculation as to their origin. It is generally agreed that the malposition of certain cells in early embryonic life accounts for their occurrence. There is divergence of opinion however as to which embryonic tissues are the original source.

Felix offers the strayed genital cell theory as an explanation of these lesions. He believes that the cells of the urogenital fold may not arise from differentiated coelomic cells but have their origin from the segmentation cells of early fetal life. These cells leave the region of the cloaca going to the root of the mesentery, and from this point to the urogenital fold. The failure of these cells to reach the urogenital fold is thought to account for the occurrence of these cysts. This view explains readily the occurrence of retroperitoneal dermoid cysts, but Webb-Johnson and Muir raise the point that the absence of all three germinal layers removes pancreatic cystadenomata from this category of teratomatous tumors. Ewing, however, has pointed out that one layer may predominate in such tumors to the almost total exclusion of the other two. A second view somewhat closely allied to the foregoing is that these cysts represent remnants of the mesonephros which have persisted to undergo proliferation during adult life. A third explanation offered is that they represent abnormal budding off from the gut during fetal life.

While none of the embryological mechanisms are entirely satisfactory, the strayed genital cell theory of Felix has the widest acceptance. In view of the variations in pathology it would seem logical to conclude that those showing characteristics closely resembling teratomata or ovarian tissue have their seat of origin in ectopic genital cells of fetal life. On the other hand those showing close resemblance to pancreatic tissue may well have had their origin from some abnormal budding out process of the primitive gut.

The clinical picture presented by cystadenomata differs in no way from other pancreatic cysts. They are essentially a disease of middle life. The most constant symptoms are pain and abdominal enlargement. The pain is generally in the epigastrium or left upper quadrant and does not simulate that of other abdominal conditions. The mass also is in no way distinctive. The size is quite variable and the contour may be smooth or irregular. Mobility is a frequent finding but in the case presented here this was very misleading as at operation the cyst extended into the pancreas on a broad base and was fixed tightly. Masses in the sites commonly occupied must be differentiated from growths in the stomach and colon, renal tumors, circumscribed enlargements of the liver, and other retroperitoneal growths. There are no constantly found associated diseases in this condition, although the case presented here had an accompanying diabetes of seven years duration. There are no diagnostic physical signs and no diagnostic laboratory procedures, the diagnosis if made, being by the process of exclusion of other possibilities.

Marsupialization or drainage of pancreatic cysts is a universally accepted surgical procedure. Judd, however, emphasized the importance of selection of proper cases for excision of the cyst. Examination of the literature reveals excellent results by drainage of the cysts unassociated with epithelial proliferation. However, those cysts which are lined with secretory epithe-

Approved by the Publications' Committee.

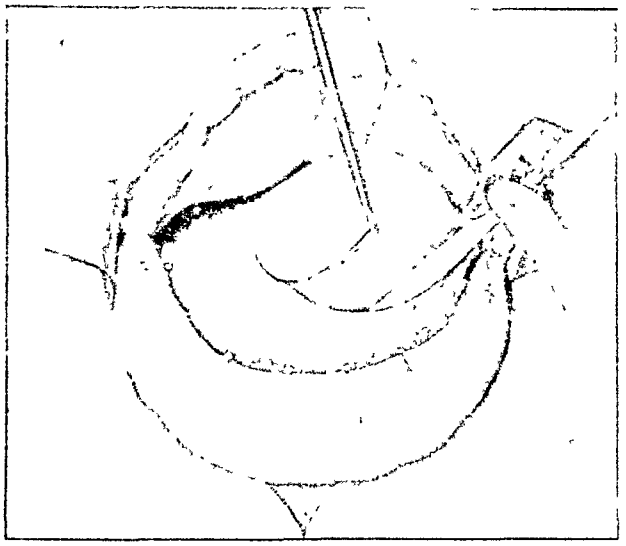

Fig. 1. Subcapsular removal of cystadenomata of pancreas.

lium do not become obliterated in the usual four to six months time, but remain quiescent for varying periods only to open up again. Mahorner and Mattson cite a case having recurrences of multiple cysts for which he was operated upon six times with death five years after the first operation. Speese reports one case of cystadenoma treated by drainage with recurrence ten years after operation. Hamilton reports one case drained in which radiotherapy was necessary to stop the continual discharge from the sinus where drainage had been instituted. In view of these facts excision, wherever technically possible, should be the surgical goal in the treatment of these cases.

Malignant degeneration with an extension to the surrounding tissues through the inflammatory fibrous wall makes it impossible to remove the growth. An excision of the cyst by separating the outer cyst wall from the pancreatic structure was considered impossible in the case presented. The density of the junction of cyst to surrounding structure together with the inability to establish a line of cleavage at this point made the operation as shown in Fig. 1 seem to be the only possible method for removal. Had the cyst been malignant and extension to the inflammatory capsule taken place before operation the entire growth would not have been removed by this method.

The method as shown is very similar to the common subserous removal of the acutely inflamed gall bladder. The wall of the cyst was obviously thick and edematous presenting very much the same picture as the serous surface of an acutely inflamed gall bladder.

An incision into the wall of the cyst about one-quarter inch from the pancreatic tissue margin was made half way around the inferior border of the cyst. One must judge the thickness of the cyst wall and carry the incision into the wall only sufficiently to establish a line of cleavage. Grasping the upper margin of the line of incision in nosed clamps enables traction to be placed on the cyst. The lower margin is bluntly forced away from the cyst and a line of cleavage established. As soon as the line is well established, the dissecting finger carries on as the cyst is retracted forward and upward. The dense fibrous tissue yields

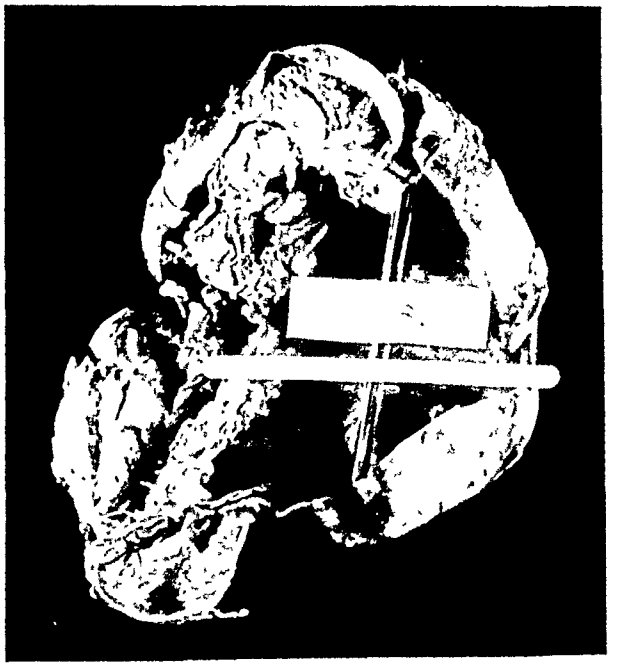

Fig. 3

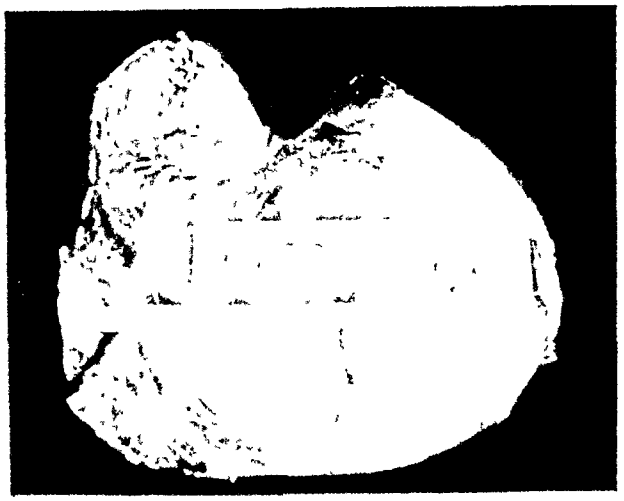

Fig. 2

to splitting because of the edematous nature of its structure.

In the fibrous tissue wall there was encountered toward the mid-line several venous sinuses that bled profusely just before the cyst was lifted out. Those in the margin of the cyst wall were clamped but could not be tied because of the dense fibrous tissue. The clamps were left in place, the center of the cavity was packed with gauze. The clamps and packing were brought up through the opening in the gastro-colic omentum and left protruding through the center of the incision.

On the fourth day post-operative the clamps were unlocked and as no bleeding occurred they were removed the following day. Hemorrhage was rather profuse at operation and blood transfusion for secondary anemia was performed the week following operation. The gauze packing was removed on the ninth day with the patient in the operating room so that repacking could be done in case of bleeding. No further packing

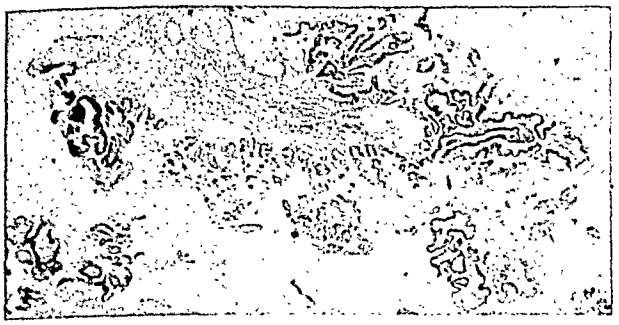

Fig. 5

was necessary and the wound healed by secondary union. The patient was discharged from the hospital on the 24th post-operative day.

CASE REPORT

R. O., a 48 year old Jewish housewife, complaining of mild generalized abdominal pain of an aching character for eighteen months. This was unrelated to meals and was unassociated with any other symptoms. One year before admission she was in another hospital where a mass was found in the left upper quadrant and operation advised. This was refused and following discharge she was well except for weekly attacks of pain.

She had been a mild diabetic of seven years duration and had been easily controlled by dietary management. Two months before admission she began to complain of paresthesias of the extremities and at this time urinalysis showed glycosuria. As these symptoms continued with ambulatory treatment she was advised to enter the hospital for a general checking over of the diabetic situation.

Physical examination showed a well nourished obese woman of middle age, who had no physical abnormalities other than those found in the abdomen. In the left upper quadrant there was a hard, irregular, freely movable, non-tender mass about 10 by 8 cm. in size. The mass moved with respiration and on percussion a dull note was obtained over it.

Laboratory findings: A flat plate of the abdomen showed an ovoid mass 12 cm. in diameter occupying the left upper quadrant, distinctly demarcated from the spleen and the left kidney. There were nodules present about the periphery of the mass and faint calcareous deposits were noted on the superior and medial sides.

The blood picture was normal showing R.B.C. 4,670,000,

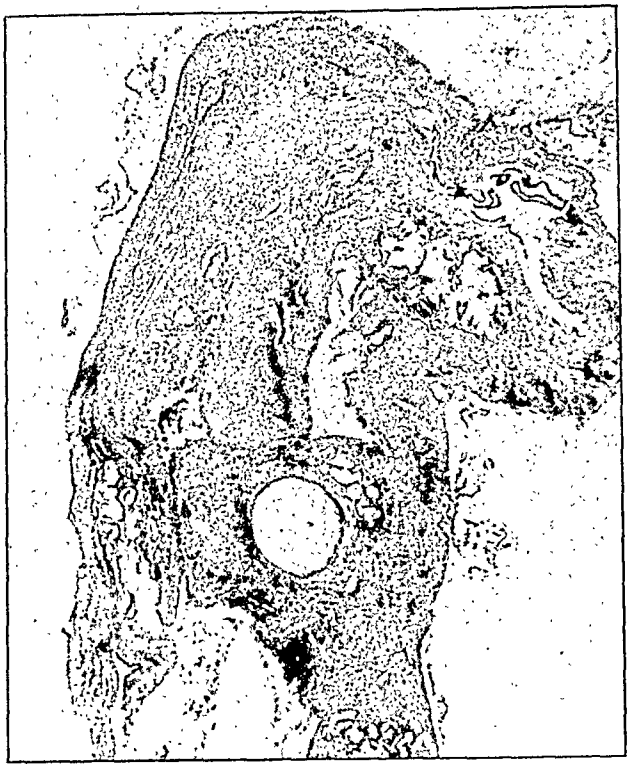

Fig. 4

Hemoglobin 88 per cent, W.B.C. 7500, with normal differential. No parasites were found in the stained smear.

Chemical examination of the blood showed non-protein nitrogen of 36.6 mg. per 100 c.c., urea nitrogen 13.5 mg. per 100 c.c., sugar 162 mg. per 100 c.c., cholesterol 270 mg. per 100 c.c., and a CO_2 combining power of 67.3 volumes per cent.

The blood Wasserman was negative.

IN MEMORIAM

John Bryant*

By

FRANKLIN W. WHITE, M.D.

BOSTON, MASSACHUSETTS

It is hard to lose our older men; it is doubly hard to lose one of our younger, vigorous men, in his prime.

John Bryant was born on our New England seacoast at Cohasset, Massachusetts, of old New England stock. He graduated from Harvard College and Harvard Medical School. He was a sailor, which always endeared him to me, with a spirit of adventure, and delighted in long cruises in small boats. He spent two years abroad and his research work in Vienna bore

*Delivered before the Thirty-Ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-6, 1936.

fruit in some of his most quoted papers on the measurements of the intestines. He had a long military service during the war, beginning with the rank of Captain and ending with the rank of Major. He was greatly interested in problems of convalescence and wrote valuable papers on this subject, as well as a book entitled, "Convalescence: Historical and Practical" (1927).

He was a consultant of the Burke Foundation for Convalescents, New York City, and Medical Assistant in Problems of Convalescence at the Massachusetts General Hospital. He was also Assistant Physician at the Robert Brigham Hospital in Boston.

John Bryant's genial, happy disposition, his tact and kindness, endeared him to his many patients and enabled him to work wonders with that difficult group of asthenias affected with gastro-intestinal symptoms. He has written a series of valuable papers on the Intestinal Neuroses.

As you all know, John Bryant was a devoted secretary to our Association for a period of four years (1923 to 1926, inclusive), always painstaking and thorough, doing everything possible to advance the interests and standing of our Association. The careful revision of our Constitution and By-Laws in 1921 was entirely his idea and largely carried out by him. He was a valuable member of our Council and later was elected President. It was a tragedy that this honor came at a time in his life when illness prevented him from presiding at the Annual Session.

The going of John Bryant takes from our Association an active, valuable, and much loved member.

Lafayette Benedict Mendel: An Appreciation*

By
VICTOR C. MYERS, Ph.D., D.Sc.
PALA ALTA, CALIFORNIA

Lafayette Benedict Mendel was born at Delhi, N. Y., February 5, 1872, the son of Benedict and Pauline (Ullman) Mendel, highly respected citizens of Delhi. The town of Mendel's birth was very proud of the record he subsequently made. He was appreciative of this evidence of affection, and continued to return to Delhi for his summers until overtaken by his tragic fatal illness two years ago. He died on December 10, 1935.

Lafayette Mendel's interest in physiological chemistry was aroused by Professor Russell H. Chittenden under whom he took his Ph.D. degree in 1893 at the early age of 21. After serving as an instructor for two years he spent the two following years in various laboratories in Germany on leave of absence, then returned to Professor Chittenden's department at Yale and advanced through the various grades to a full professorship in 1903 and to the newly created Sterling Professorship of Physiological Chemistry in 1920.

Professor Mendel received nearly every honor which could be conferred upon him, a partial list of which will be given. He was a member of the National Academy of Sciences, the American Philosophical Society, an Active Member of this Association from 1907-1930, an Honorary Member since 1930, and numerous other scientific societies both here and abroad. He served as President of the American Society of Biological Chemists and the American Institute of Nutrition. He was a member of the Council on Pharmacy and Chemistry, and of the Committee on Foods of the American Medical Association. He served the U. S. Government in many advisory capacities during the World War, and also represented it on the Interallied Food Commission abroad. He was a member of President Hoover's White House Conference on Child Welfare and Development. He served as an Editor of the *Journal of Biological Chemistry*, *Journal of Nutrition*, *Chemical Reviews* and was a frequent unofficial contributor to the editorial pages of the *Journal of the American Medical Association*. He gave the Herter lectures at New York University, the Hitchcock lectures at California, the Schiff lectures at Cornell, the Cutter lectures at Harvard and twice lectured be-

LAFAYETTE BENEDICT MENDEL

*Presented before the Thirty-Ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936.

fore the Harvey Society. In 1934, the Chemists' Club of New York awarded him the Conne medal for outstanding chemical service to medicine. He received the honorary degree of Sc.D. from Michigan and Rutgers and that of LL.D. from Western Reserve University. In his own University he served as a member of the Governing Board of the Sheffield Scientific School and of the Board of Permanent Officers of the Graduate School and School of Medicine. On his sixtieth birthday his students and friends presented his portrait to the University, the former contributing to an anniversary number of the *Yale Journal of Biology and Medicine* which was dedicated to him.

Despite these many honors, Mendel's claim to greatness probably rests more upon his remarkable ability to train others than upon any other quality. I am sure that he took greater pride in this than anything else. When a student undertook a research problem, Mendel did not select some topic in his own field of research, but tried to help the student pick a problem which might be the beginning of the student's own life work. He was most unselfish in this as he was in the manner of publication. By his own unique methods he aroused and stimulated the student during the investigation. Above all he taught the student to think for himself. Good work received suitable recognition, and although mistakes and errors were not directly criticized, they never missed his eagle eye. Mendel kept in constant touch with his students after they left his laboratory, and very few there were who did not frequently turn to him for advice, which was always given promptly and cheerfully. He wrote a beautiful and very legible hand and for many years took care of his personal correspondence in this way. It was a great incentive to receive one of those witty and stimulating letters from master and friend.

Ninety-two students received the Ph.D. degree under his guidance, and these may be found actively trying to follow the example of their teacher in some of the most representative institutions of this country.

Although, in Professor Mendel's later years, nutrition may be considered his chief interest, he was always much interested in gastro-enterology, perhaps in part because of his training under Chittenden and Heidenhain. Numerous investigations in his laboratory, particularly in the earlier years, touch upon almost all phases of digestion and absorption. He was also much interested in the clinical application of this work and was frequently consulted by gastro-enterologists. As a student, I recall his referring to the work of Meltzer, Hemmeter and Einhorn, and to this Association.

For more than twenty years, however, his interest largely was in the field of nutrition. In 1919 he presented a paper before this Association on "Food Factors in Gastro-enterology," in which he stated: "It seems to me . . . that a discipline which relates to the normal and pathological conditions of the digestive organs cannot fail to find some interest in the *rôle* of the foods, for the transformation and transport of which these organs exist, or in the phenomena of nutrition for which the function of digestion is an indispensable preparation." In this way he related most of the work of his later years to gastro-enterology.

Few men exerted so wide an influence as Lafayette Mendel; very few have trained so many to "carry on" when they are gone. This Association may well be proud to have had Mendel as both an Active and an Honorary Member.

Harlow Brooks*

By

WILLIAM GERRY MORGAN, M.D.
WASHINGTON, DISTRICT OF COLUMBIA

Dr. Harlow Brooks was born at Medo, Minnesota, on March 31st, in 1871. He received his preliminary education in the High School of Medo, and later graduated from the University of Oregon. In 1895 he received the degree M.D. from the University of Michigan School of Medicine, and from the same School received the honorary degree of M.Sc. in 1930. He took post graduate study at the University of Freiberg, and at the Polyclinic in Munich. He was Assistant Demonstrator of Anatomy at the University of Michigan School of Medicine in 1895; Instructor of Histology and Embryology, Bellevue Hospital Medical College, 1895-98; Research Fellow in Bacteriology, New York State Hospitals, Pathological Institute, 1887-1920; Professor of Clinical Medicine, New York University Medical College, 1922-1929.

At the time of his death Dr. Brooks was Emeritus Professor of Clinical Medicine, New York University Medical College; Visiting Physician, Bellevue Hospital; Consulting Physician, New York City, French, New York Polyclinic, Union, Fifth Avenue, Hackensack, New Jersey, Beth Isreal, Greenwich, Mount Vernon, Saint John's, Southside (Bay Shore) Flushing, Jamaica, Bronxville and Montefiore Hospitals, Hospital for Joint Diseases and Norwegian Lutheran, Deaconess's Home and Hospital. His World War record: Major, Lieut. Colonel and Colonel, M.C.U.S.A.; Chief of Medical Service Base Hospital, Camp Upton; Chief Consultant in Medicine First Army Corps, A.E.F.; Senior Consultant in Medicine, Second Army Corps, A.E.F.; Awarded Distinguished Service Medal, General Citation. He was a member of the American Legion and of the Association of Military Surgeons.

He was a member of the Phi Alpha Sigma fraternity; Member of the Harvey Society, Society of Experimental Biology and Medicine, Association of American Physicians, American Medical Association, American Gastro-enterological Association, Medical Society of the State of New York, New York County

*Delivered before the Thirty-Ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936.

Medical Society, and the American College of Physicians. He was elected Fellow of the American College of Physicians at its first regular meeting held in New York in December, 1916. He was elected President in 1923 in which capacity he served for two years. In 1925 he was elected to the Board of Regents where he served for three years; in 1929 he was elected to the Board of Governors on which he served for two years. He also served on various committees and gave generously of his time and energies to the work of the College.

Dr. Brooks was a prolific writer and published many monographs and special articles on medical and biological subjects. He was the Editor of Lippincott's Everyday Practice Series.

He was keenly interested in animal life, exploration, mountaineering and was an honorary Fellow in the New York Zoological Society and a member of the Explorer's Club, Adventurer's Club, and the Camp Fire of America.

Dr. Brooks was one of the outstanding diagnosticians of his time and was called in consultation as frequently probably, as any other doctor in the United States. He was looked upon as an authority in diseases of the circulatory system. He was often referred to as the "doctors' doctor," being constantly sought by his brother practitioners in cases involving their immediate families, among whom he was known as the "Beloved Physician."

Few physicians of his time gave so generously of their services to the poor.

As a young pathologist, Dr. Brooks collaberated with Dr. William Welch at Bellevue Hospital in advanced research work that resulted in the discovery of the bacillus named after Dr. Welch which is responsible for the disease commonly called "gas bacillus" infection, and which, by a curious coincidence was the cause of Dr. Brooks' own death.

One of the contributing factors which enabled Dr. Brooks to maintain his enthusiasm for his profession and for life in general was his devotion to his hobbies which were very varied. He was a skilled musician and a collector of outstanding works of art, as well as being an anthropologist of note. His collection of Indian relics surpassed any similar private collection in the world; it contained some specimens not to be found in any other collection.

Probably his great physical stamina was due, in part at least, to his love for fishing and hunting, in each of which he was an outstanding expert. Often Dr. Brooks would remark that he gladly devoted ten months each year to the pursuit of his profession but retained two months to seek recuperation and happiness in the great open spaces.

One of the outstanding characteristics of this great physician was his genius for friendship. His friendship was a living vital force upon which rested profound gratification and innermost happiness. When Dr. Brooks bestowed his friendship it was for the duration of life. He was truly catholic in these friendships which were confined to no one profession or social stratum. Caring little for individual accomplishments, Dr. Brooks demanded honesty, frankness, and I was about to add, loyalty in his friends. However, since loyalty is the quintessence of true friendship, it may be omitted.

I have somewhat stressed this phase of Dr. Brooks' character because to him it was the dominating influence of his life, and also, because in these times of emotional upheaval and cross purposes the gift of true friendship is a God-given attribute which is all too rare.

And so, from our midst, has been taken this great physician, this talented gentleman, this indefatigable worker, this scientist of renown, this man of many enthusiasms, of loyal friendships, of kindly heart and broad sympathies—gifted in so many ways and with so many talents that the world, indeed, is richer for his having lived in it. Those who had the privilege of close association with Harlow Brooks will carry in their hearts ever the memory of his cheering and inspiring presence and the light of his Christian spirit.

Henry Wald Bettmann*

By

LEON SCHIFF, M.D.
CINCINNATI, OHIO

Dr. Henry Wald Bettmann, senior member and President of the American Gastro-enterological Association, died on December 4, 1935, of coronary artery disease.

Dr. Bettmann was born in Cincinnati, Ohio, on January 14, 1868, the son of Matilda Wald and Bernhard Bettmann. In 1887 he received his A.B. degree from the University of Cincinnati and was elected to Phi Beta Kappa. Three years later he was graduated, with honorable mention, from the Medical College of Ohio. After a year's interneship in the Cincinnati General Hospital, he spent two years in graduate study in the clinics of Berlin, Prague and Vienna.

In 1893 he was given the appointment of "Curator of the Laboratory" at the Cincinnati General Hospital. While serving in this capacity he originated the first city-wide service for the bacteriological diagnosis of diphtheria. At the same time, with the help of several colleagues, he opened a course in clinical laboratory methods for practitioners. He was appointed pathologist to the Cincinnati General Hospital in 1894, which position he held until 1907.

Early in his career, Bettmann's interests began to lean toward the field of gastro-intestinal diseases. In 1903 he received the prize for a monograph on studies of the shape and position of the stomach. In 1904 he was elected Second Vice-President of the American Gastro-enterological Association and served as President during the years of 1905 and 1906.

*Delivered before the Thirty-Ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-6, 1936.

Dr. Bettmann made numerous contributions to the subject of diseases of the digestive tract and was particularly interested in the problem of so-called chronic appendicitis with particular reference to the pit-falls in the diagnosis of this condition as evidenced, for example, by the failures following surgical treatment. He was, up until the time of his death, engaged in a large practice much of which was consulting in character.

He wrote the chapters on Diseases of the Liver and Diseases of the Intestines for the George Blumer edition of *Forcheimer-Billings Therapeusis of Internal Diseases*. He wrote the section on Diarrhea for Nelson's *Loose-Leaf Medicine* and the section on Examination of the Feces in Tice's *System of Medicine*.

Dr. Bettmann was a friend of the younger medical man and would constantly encourage him in his undertakings. He was a man of diversified interests. His knowledge of literature, both ancient and modern, was profound. Both the fields of poetry and philosophy were his in which to wander and a remarkably tenacious memory made what he read his own possession. He was a chess enthusiast of the highest order; he delighted in setting and solving the most intricate problems. His was a mind which lent itself naturally to a culture of uncommonly wide extent. Endowed with a delightful sense of humor, his qualities made him a colleague to be loved and cherished; his humanitarianism and ability, one to be admired.

His passing represents a distinct loss to this Association.

George Washington McCaskey*

By

WILLIAM GERRY MORGAN, M.D.
WASHINGTON, DISTRICT OF COLUMBIA

Through the death of George Washington McCaskey in Fort Wayne, Indiana, on December 30th, 1935, the American Gastro-enterological Association lost one of its earliest and most distinguished members.

Dr. McCaskey was born in Fulton County, Ohio, November 9, 1853. He was graduated from the Jefferson Medical College in 1877 and in 1880 from the University College of London, England. Upon his return to his native land he established his practice in Fort Wayne, Indiana, where he continued his life work up to the time of his death. He retired from clinical work seven years ago, to devote himself to writing and to research.

By his untiring devotion to the pursuit of knowledge in his chosen profession, Dr. McCaskey won a high place as a diagnostician and clinician, and was a recognized authority in diseases of the alimentary tract.

Dr. McCaskey was a prolific writer and his contributions to medical literature were numerous and valuable.

In 1910, Dr. McCaskey was a delegate to the International Medical Congress at Madrid, Spain, at which he delivered a noteworthy address.

Dr. McCaskey had several honorary degrees conferred upon him in recognition of his professional attainments, among which were Ph.B. in 1881 and M.A. in 1884, both by the DePauw University.

Dr. McCaskey by his broad vision, keen judgment and wise council won the confidence and esteem of those with whom he worked for so many years.

Be it Resolved: That we, the American Gastro-enterological Association express our deep sorrow for the loss of this true physician and wise counselor.

Be it Further Resolved: That these resolutions be made a part of the permanent records of this Association, and a copy be sent to the surviving members of Dr. McCaskey's family as a token of the high regard and esteem in which he was held by the members of the American Gastro-enterological Association.

*Delivered before the Thirty-Ninth Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., May 4-5, 1936.

Annual Abstracts of Proctologic Literature, 1935-1937

By CHARLES E. POPE, M.D., Evanston, Illinois

INTRODUCTION

IN the performance of my duty in the review of the Proctologic Literature for the past year, it was immediately evident that the task was nearly Herculean and apparently never ending. That satisfaction that comes with the exhausting completion of a single subject for review is not the reward of the compiler of the Proctologic Literature for this Society. To do that is a physical impossibility and with the added interest given our specialty and the increasingly large numbers of contributions, coupled with the importance of having a careful analysis of the literature on the multitude of related subjects, there might be some question as to the wisdom of delegating the work to a single member of the Society in the future.

As it has been with my predecessors, additional help always has been necessary from librarians and from abstractors for both foreign and domestic abstracts; and each one has mentioned that, though a voluminous report was given, nevertheless it was by necessity many hundreds of articles less in the Transactions than the number actually reviewed. My respectful admiration and appreciation of past reviewers rapidly mounted at the start of this work last year.

Whereas this is merely offered as a suggestion for your future consideration one definite change was made following the suggestion of the secretary,

to carry the review to the present year and not beyond. This year's review therefore commences in May, 1935, and carries to January, 1936, whereas next year's review should be wholly a 1936 review.

GENERAL

Dr. Frank Smithies through the American Journal of Digestive Diseases and Nutrition as his spokesman has written one of the finest editorials on our specialty that the writer has had the privilege of enjoying. The just prominence and attainments of the author adds greatly to the importance of the article, and the article itself does much to further proctology.

Cecil Gaston emphasizes the need for the advancement of proctology and illustrates the excellence of that department in the South Highlands Infirmary in Birmingham.

Gaston, C. D.: The Department of Proctology. South Highlands Infirmary, Birmingham, Ala., Oct., 1935.
Smithies, F.: Proctology: A Specialty, and Its Influence Upon This Journal's Publication Policy. *Am. J. Dig. Dis. and Nutrit.*, 2:635, No. 10, 1935.

ADENOMAS

This subject is also discussed in papers on related subjects and in papers on electro-coagulation.

Fansler discusses advanced as well as early cases. Lesions visualized within the last 25 cm. of bowel are the pedunculated adenomas and the flat or button type which are particularly prone to malignancy. The pedunculated may be fibrous and therefore non-malignant or may be villous or papillary.

Geschickter in a review of 178 cases of benign tumors of the gastro-intestinal tract found a total of 90 adenomas of which 10 were colon and 55 rectal. In the malignant group, however, this relative proportion changed for in a series of 1472 malignant tumors, 250 were colon and 370 were rectal.

Lockhart-Mummery believes that the simple adenoma is merely a stage in the development of malignancy. In 50 cases a recurrence was present in half of the cases. The author believes that gene mutation occurs in a cell nucleus resulting in excessive reproduction.

Mandillon and *Georget* believe that diffuse intestinal polyposis and the localized form have an irritative infectious origin but an etiology and pathogene-is still uncertain and that whether they constitute two different degrees of the same affection or two different diseases present knowledge does not permit to say.

Nystrom reports 7 cases of diffuse polyposis of the rectum and colon. Four cases died from cancer and 2 pairs occurred in brothers.

Oppolzer reports a case of papillomatous polyps in the cecum which recurred following a cecal fistulectomy performed 2 years following appendectomy. Chronic inflammatory irritation from long pus discharge and intramural resorption played a definite part as a causal factor.

Rankin reviews 11 cases of adenomatosis 6 of which were previously reported. The present 5 were complicated by ulcerative colitis. Discusses the surgical aspects. One case had fulguration and a reestablishment of bowel continuity by operation.

Rankin, F. W.: Colectomy for Adenomatosis and Pseudopolyposis: Report of Five Additional Cases. *Ann. Surg.*, 102:707, Oct., 1935.

AGRANULOCYTOSIS

Küpper reviews 327 cases from 43 different observers—German, English, French, American, and Norse, and includes sixteen of his own cases and concludes that the disease is 3 times as frequent in the female, occurs most frequently between 30 and 60, shows an average mortality of 75% (94% of authors own cases), and that therapy is of little value.

Kracke and *Parker* review the literature and conclude that amidopyrine, dinitrophenol, and closely related drugs are responsible as etiologic factors.

Norris reviews 76 cases. The mortality was 79% and the average age 41.

AMEBIASIS AND PARASITIC INFECTIONS

AMEBIASIS. Amebiasis showed itself to be endemic and sporadic in occurrence during 1935. Increased recognition of the disease in other stages than its dysenteric form is encouraging. Experimental work has given interesting and apparently very practical and constructive knowledge of the endamoeba histolytica. Therapy is little changed from previous methods and favors combined medication.

EXPERIMENTAL AND INCIDENCE. *Spectors* found that freshly isolated pathogenic organisms in man when inoculated with endamoeba histolytica in the kitten increased both the severity and the extent of ulcerations so produced. This was most marked with the hemolytic streptococci and occurred likewise but to a lessened extent with pneumococcus Types I and III and a green producing streptococcus from ulcerative colitis. When, however, prolonged cultivations of the endameba histolytica and hemolytic streptococcus were used the mortality and the degree of ulceration produced experimentally was markedly reduced. The work was done in careful detail and well controlled.

Nauss suspects that intestinal bacteria play an important role likewise inasmuch as his experimental inoculation of new cultures of endameba histolytica alone or with hemolytic b. coli in kittens were most apt to produce infection. He suspects therefore that only grossly contaminated water and food produce epidemics as in Chicago and that carriers do not play an important part, but that in the individual cases occur mainly because of a depressed resisting power of the gut. The author reviews the incidence of protozoa including endamoeba histolytica in 850 routine examinations and by sigmoidoscopy as well as by removal of material proctoscopically in 270 cases. Repeat examination increased the incidence of endameba histolytica 50% which for food handlers should be 9-10%.

Stites agrees with this incidence and from personal observations states the incubation period whereas quoted as 10-100 days may be as early as 48 hours.

Wenrich, *Stabler* and *Arnett* in a study of 1060 students from 1930-1933 report 4.1% harbor endameba histolytica whereas 34.5% harbor protozoa. Permanent slides gave more positives than wet preparations. Stools were used.

COMPLICATIONS. *Anderson* condemns the use of emetin for other than in amebic hepatitis or abscess or where complications requiring surgical intervention necessitate it due to danger of permanent cardiac damage. Advocates local excision of granulomas or rectal pathology (ulcer) if such exist. States refractory cases occupy 10% of his cases and advocates appendicostomy for continuous irrigations of the colon. His discussants notably William Boack did not agree with him regarding the non-use of emetin.

Guichard and *Paponet* report a case showing inflammatory polyposis. Biopsy from an apparent "rectal adenoma" confirmed the clinical impression. The neoplasm disappeared on emetin and Stovarsol treatment.

Meleney and *Meleney* report an unusual case of gangrene of the buttocks, perineum and scrotum due to the lytic action of the endameba histolytica and not accompanied by other bacterial invasion. Skin graft was necessary.

TREATMENT. *Brown* and *Magath* in an excellent review of amebiasis state that the complement fixation test is as

yet too complicated for routine use and that cultural methods offer a good method excepting that characteristics of the cultured amebae are not well enough known. Emetin gr. 1 subcutaneously twice daily for three days is commenced with treparsol 0.25 gm. three times daily for 4 days. Three such courses are given at ten day intervals. Yatren three grams daily for a week followed by emetin and treparsol if necessary and repeated in a week is given for recurrence.

O'Connor and *Hulse* report excellent results in the use of iodoxyquinolin sulphonic acid (anayodin) in 152 cases. They give 4 pills three times daily for 8 days.

PROTOZOAL INFECTIONS OTHER THAN ENDAMEBA HISTOLYTICA. *de Paula E. Silva* report 22 cases of giardiasis obtained from bile in biliary drainage. Symptoms due to duodenum and biliary tract were present.

Gabaldon experimented on rats with strains of balantidium coli. No reference to human cases is made.

Gachlinger found lambliasis in vegetative form 70 times and their cysts 32 times in examining 318 cases of chronic colitis. Endameba histolytica was found in vegetative form 4 times and encysted 11 times in the same 318 cases. The frequency of lambliasis explains the frequency of favorable results in the use of arsenical treatment of cases.

Savy et al cite a case of hemorrhagic rectocolitis in which the feces showed ascaris eggs. Intravenous thiosulphate caused complete cure.

ANATOMY

Hiller states that the confusion existing concerning the white line of Hilton is that post mortem findings are not as in vitro, that it is identical with the pecten of Stroud. Because of poor vascularity it shows as a white line representing fibrous tissue deposit beneath the uncornfied epithelium at the termination of the muscularis mucosae.

Tucker and *Hellwig* give an excellent contribution to our knowledge of the anal ducts based on a study of the anal histology in the dog, cat, guinea-pig, rabbit, and chicken and on longitudinal sections of six human embryos. This comparative study as well as the study of pathological specimens of the prostate and paraurethral glands showed that the anal prostate and paraurethral ducts are hemologous structures, develop in the embryo at the same time and arise from the anal intermediate zone and urogenital sinus respectively, which in turn are cloacal in origin. The anal ducts are vestigial remnants of the larger glands seen in the intermediate zone of the anal canal as a complex gland in the dog, pig, and rabbit, and a cloacal gland in the chicken. Pathologically the ducts are apt to harbor gonococci as is the case in the prostate and paraurethral glands.

ANESTHESIA

Lundy discusses the extent to which the inexperienced person may be justified in using certain anesthetic agents and reviews these drugs from this viewpoint.

NEW ANESTHESIAS. *Lundy* describes a new form of anesthesia where two or even three times the usual 30 c.c. of a 1% procaine solution may be injected into the caudal canal. It may be reinforced with second sacral foramina injections. Campbell states 70 cases have been tried at the Mayo Clinic since January 1, 1935, of which 6 were anal or rectal. 30 minutes or more is required for anesthesia. Sacral anesthesia was satisfactory in 96% of 10,960 cases at the Mayo Clinic from 1924 to 1934. Lundy in his discussion includes an extensive and complete bibliography on the subject.

Lundy describes two new barbiturates for short profound general anesthesia for use intravenously. Operations lasting 10 to 15 minutes are satisfactory for these drugs. The drugs are termed Barbiturate A and B, the former being more profound is the more satisfactory and is sodium ethyl 1 methyl butyl thiobarbituric acid. The drug is termed

Creamalin

Therapy in

PEPTIC ULCER

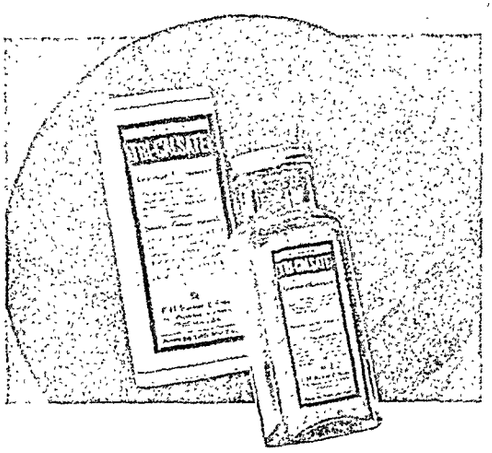
Accompanied by

Hypochromic Anemia

Recent investigation has shown that an iron-rich diet had practically no effect on the formation of hemoglobin during the period of alkalinization such as in a Sippy regimen, but that after the administration of alkalis was stopped it had a marked effect.

Kellogg and Mettier (Arch. Int. Med., 58:278-Aug., 1936) have demonstrated that "alkalinization of the upper part of the gastro-intestinal tract interferes with the utilization of dietary iron for the synthesis of hemoglobin," and delays recovery from the anemia.

Creamalin, a specially prepared amphoteric colloidal cream of aluminum hydroxide, is not an alkali and therefore will not produce an alkalinization of the upper part of the gastro-intestinal tract.



Creamalin has now been used in thousands of cases of gastro-duodenal ulcer with gratifying results. Many of the cases treated were resistant to therapies based on combating the acid factor by chemo-neutralization. The special technique employed in preparing Creamalin yields a product of unusual antacid action — *one volume combining with fourteen volumes of N/10 HCl in one hour by physical fixation.*

Creamalin therapy should be considered in all refractory cases of gastro-duodenal ulcer. It can be administered orally or as a continuous drip using the new Creamalin Automatic Drip Control. Write for literature and material for clinical trial.

Cleveland, Ohio

AVOID

The Vicious Circle of Alkali Neutralization

TRI-CALSATE

Neutralizes gastric HCl . . . yet does not stimulate gastric secretion or alkalize the stomach contents. The buffering effect of its end salts protects against harmful alkalosis.

Non-toxic . . . non-irritating . . . palatable. The possibility of gastro-intestinal irritation is remote . . . the kidneys are unharmed.

ECONOMICAL. The quantity in the large size bottle has been increased from 16 to 18 oz. at no increase in price, making in effect a ten per cent reduction in price to the patient.

TRI-CALSATE is available on prescription at your pharmacy or direct in 4 oz. and 18 oz. bottles.

We will be pleased to send you literature and a trial supply of Tri-Calsate, upon request.

pentathal and is to be supplied by Abbott in July.

SPINAL ANESTHESIA. *Sise* advises the use of pontocaine with 10% glucose in 4 to 4½ c.c. amounts as a rapid, accurate and safe method of spinal anesthesia.

Stein and *Tovell* report their observations regarding the indications, contra-indications and technique of spinal anesthesia and report the incidence of headaches occurring postoperatively.

Anderson reports an unfortunate case of trophoneurotic gangrene of the extremity following spinal anesthesia. States 18 such cases have been reported since 1906.

OIL ANESTHESIA. (Also see Fissure and Pruritus). *Morgan* cites the results of 100 cases where satisfactory anesthesia was obtained in anal surgery in the use of almond oil containing 1.5% procaine hydrochloride, 6% butyl-para-aminobenzoate and 5% benzyl alcohol. Uses 20-30 c.c. and obtains anesthesia 7-28 days and relaxation 5-16 days.

OTHER DRUGS. *F. C. Smith* reports on the use of diothane in 73 cases where the anesthetic was used in at least 5 c.c. amounts for office excision work and combined with general anesthesia to allay postoperative pain.

Nathanson and *Daland* studied the effects of dilaudid in 115 cases and report it acts twice as rapidly as other narcotics, had little hypnotic effect, and but little effect on the gastro-intestinal tract. It, however, causes respiratory depression. Rectal suppository action was better than the usual opiates, being more rapid and prolonged given with aspirin, oral effect was better than aspirin and codeine.

ANUS AND RECTUM

GENERAL. There are a number of papers that are written on this subject and cannot be included under any separate heading. For the most part they are written for the information of the general practitioner.

Of outstanding importance is that of *Buie's* who emphasizes the necessity of differentiating functional from pathological constipation, determining the source of bleeding and distinguishing types of rectal pain.

Mechling gives a very careful review of anorectal lesions, touching upon the anatomy, embryology, and correlating that with the pathological. Campbell and Fischer write papers excellent from this viewpoint.

Buie, L. A.: Basic Facts Concerning Rectal Complaints in General and Hemorrhoids in Particular. S. Clin. North America, 15:1183, Oct., 1935.
Mechling, C. C.: Interpretation of Anorectal Complaint. *Internat. J. Med. and Surg.*, 48:203, May-June, 1935.

BLEEDING. *E. A. Daniels* discusses rectal hemorrhage and advocates the use of 5% phenol in almond oil as an injection medium therapeutically as well as diagnostically.

Weitkamp distinguishes the different types of blood passed rectally as a determining diagnostic aid. Thus anorectal pathology usually shows bright red blood, blood mixed with pus or mucus signifies the various dysenteries, malignancies, stricture, lymphogranuloma inguinale, polyposis, trauma, and in some cases diverticulitis, and dark or tarry blood high gastro-intestinal pathology.

IN VOMITING OF INFANTS

KNOX GELATINE

REDUCES MILK CURD TENSION 50%

With gelatine, soft, floculent milk curds

Without gelatine, hard, indigestible milk curds

U.S.P. GELATINE

IT'S MANY VALUABLE USES IN

PEDIATRIC PRACTICE

KNOX

SPARKLING

GELATINE

ACCEPTED AMERICAN MEDICAL ASSN.

ONE per cent of Knox Gelatine added to the formula reduces milk curd tension over 50%. The curds instead of being tough and leathery, are emulsified—made softer and finer. This is an obvious advantage in vomiting.

Colloidal Protection—Knox Gelatine has an effective colloidal action. It helps to emulsify ingested fats. Gelatine also serves as a protective agent when combined with fruit juices or with strained and raw foods.

Growth Promotion—Knox Gelatine contains 85% of easily digested and assimilated protein, rich in lysine—a growth-promoting amino acid. Thus, it is a valuable supplement to the protein content of the diet.

Knox Gelatine is made as carefully as an ampule solution, surpassing in all respects the minimum U. S. P. requirements; pH about 6.0; contains no carbohydrates; bacteriologically safe.

Formula for Modification of Milk with Knox Gelatine

Sprinkle two envelopes of Knox Gelatine on 4 ounces of cold water. Allow to soak for ten minutes. Add 6 ounces of boiling water and stir until dissolved. Add 20 ounces of milk and 1½ ounces of carbohydrate.

Send for this new, pertinent booklet. Mail coupon today.

CRYPTITIS — PAPILLITIS — PECTENOSIS. *Hirschman* gives a great impetus to proctology by an excellent contribution on the anal crypt as a focus of infection. The paper is masterful and complete. He emphasizes the necessity of crypt investigation and eradication as well as in some cases culture for vaccine therapy. A description is given in detail of the technique of culture and complement fixation, testing the organism itself for antigen or toxin producing properties. The response of the patients to the use of vaccines, etc., fall into three classes.

1. The largest group requiring surgical removal of crypts, sinuses and abscesses, and a more or less prolonged period of vaccine.

2. A class which responds to vaccine therapy in bowel functions.

3. The class of recent origin with complete response to excision. The author emphasizes the need for examination and states the necessity for recognition of cryptitis.

Hinckle discusses the crypt in relation to the pecten band and anorectal infection of various types. States that ruptured crypt in his experience is rarely the cause of a fissure-in-ano, but that infection starts the fibrotic change resulting in pectenosis and later fissure.

Bonnewitz (See Fissure-in-ano).

Papillitis and Cryptitis is reviewed by *H. Z. Hibshman* in the Cyclopedia of Medicine.

Bonnewitz, O. R.: Fissure-in-ano with Complications and Treatment. *J. Am. Inst. Homeop.*, 28:538, Sept., 1935.

Hirschman, L. J.: Perianal Suppuration as a Focus of Infection. *J. Michigan State M. Soc.*, 34:662, Nov., 1935.

FISSURE

PATHOGENESIS. *Hinkle* describes pectenosis and believes fissure developes in this fibrous band rather than from cryptic origin.

Bonewitz classifies fissures as belonging to the first, second, or third degree stage, the latter characterized by excessive fibrosis or pectenosis. Schoffield in discussing this paper emphasized that the third type was the ulcer stage and that the term pectenosis was somewhat confusing and that more frequently a cryptitis or papillitis are found on examination to be accompanying pathology in the fissure.

Blond states that a fissure is due to necrosis of an inflamed anal varicosity.

TREATMENT. *Hullsiek* in the uncomplicated fissure advocates 1-2 c.c. of 5% quinine urea hydrochloride or nupercaine in oil in 1-3 c.c. In the surgical case advocates partial external sphincter severance and the usual racket shaped wound externally.

Robb advises percain, benzyl alcohol in olive oil as an injection for simple fissure and pruritus.

Sicard describes a method of treating fissure by alcohol injection but claims no cure.

Steinberg reports a modified Gabriel sclution used with excellent results in treating 30 cases of fissure-in-ano, consisting of a nupercaine base of ½ per cent, benzyl alcohol 10%, phenol 1% in 5 c.c. of sterilized oil of sweet almond.

Silbermann reports the use of A.B.A. modified benacol solution since 1929 for anal fissure except in its ulcerated stage where surgery is then necessary.

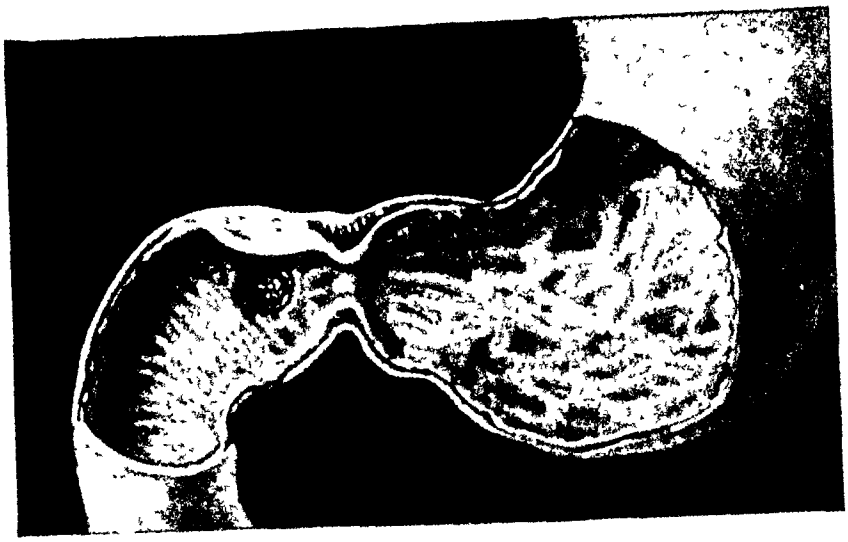
THE BOWEL

... a Source of Infection

Since the intestinal canal is a common source of systemic infection, any means of safely and effectively reducing fecal toxicity becomes a logical procedure in a host of conditions.

Morris and Dorst, Burger and other investigators have demonstrated the fact that toxic absorption from the enteric tract may be decreased by the oral administration of sodium ricinoleate—Soricin.

When given in adequate dosage over a reasonable period of time, Soricin brings relief in the treatment of mucous colitis, ulcerative colitis, spastic colitis and a wide variety of other conditions traceable to fecal toxicity, such as vertigo, anorexia, migraine, urticaria, allergic diarrhea, etc.



Soricin is non-toxic, and large doses may be given repeatedly over a prolonged period of time.

SORICIN CAPSULES
Enteric coated capsules of sodium ricinoleate, available in five-grain and ten-grain sizes.

SORICIN TABLETS (New)
Enteric coated tablets each containing five grains of sodium ricinoleate.

Sample and literature to physicians on request.

The Wm. S. Merrell Company
Cincinnati, U.S.A.

DIET-ALKALI *versus* LAROSTIDIN

The Sippy treatment, in its various modifications, is so restrictive as to be irksome to many ulcer patients. They find life a sorry burden.

With the Larostidin treatment there is a minimum of restriction. The diet is rapidly increased to normal, there is no interference with the patient's business or social duties, and there is a remarkable uplift of the spirit that has been smothered by the chronic infirmity.

It has been demonstrated*, moreover, that 70% of the diet-alkali failures make a favorable response to Larostidin. It would seem advisable to start ulcer patients on Larostidin right away.

FISTULA

ANORECTAL FISTULAE. *McKenney* reviews "Fistulas in the Anorectal Region, and Perianal and Perirectal Abscesses" in all their phases in the Cyclopedia of Medicine.

Kaufmann recommends ambulatory fistulectomy and advises destroying the absorptive surface of the mucosa, use of the seton and attempts to produce an exteriorized flat normal cicatrized wound.

Läwen describes his fistulectomy as one where the sphincters are left intact and the fistulous cavity after complete tract excision obliterated by placing silk sutures into the outer rectal ampulla and through the external wall of the cavity.

Cabanie describes his technic for fistulectomy that seems no different than many ordinarily have done. The cardinal points are complete dissection, sphincter severance, mucosal suture, sphincter suture and an open ischiorectal wound. He removes an anal drain on the 5th day.

Gordon-Watson and *Dodd* explain the course of many fistulas and abscesses by reason of perianal intramuscular glands present deep to the internal sphincter which are for the most part vestigial remains of a more highly developed prenatal duct and gland. They explain the cause of many a deep seated pelvirectal abscess and fistula on this basis and state their removal is necessary for cure to be effected.

W. J. Martin, Jr., in an excellent paper on fistula-in-ano states the cure should be over 95%. Failures are commonly due to excision or incision of the tract with suture of the internal opening or failure of internal opening excision because not found. The paper details many practical aids for the general practitioner.

Prioleau cautions against early sphincter division where the sphincter ani is extensively involved.

Wintsch advises that two stage operations in the treatment of the complex fistula may be necessary but when careful dissection is done on stage suffices. Several cases are given in detail.

INTESTINAL FISTULAE. A traumatic rectojejunal fistula is reported by *Caeiro*. It resulted from a fall on a wire fence with perforation through the anus.

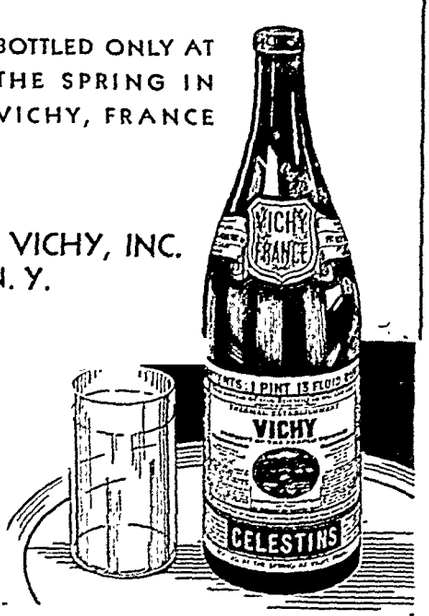
Leland cites a simple vesical calculus resulting in transverse colon fistula.

Raiboff reports a renocolic fistula.

Ranson and *Coller* record 94 cases of external intestinal fistulae other than artificial anus, rectovaginal, and enterovesical fistulae. 13 were tuberculous, one was actinomycosis, 30 were associated with appendicitis, 7 cases of which were cecal or sigmoid, and 10 were undeterminable origin.

Saleh reports a rare case of duodenocolic fistula from carcinoma of the hepatic flexure.

Scott reports 6 cases of rectal trauma, one of which resulted in rectourethral fistula. The repairs were all made at the time of injury excepting



DYSPEPSIA Complicating ARTHRITIS

DYSPEPSIA in persons with the uric acid diathesis, or other forms of nitrogen excess in the system, is especially amenable to treatment with Vichy Celestins. Indeed, in all forms of dyspepsia, other than those arising from cancer or gastric or duodenal ulcer, physicians have found Vichy Celestins of distinct service.

A generous supply of Vichy Celestins and a booklet on its therapeutic value, with medical bibliography, will be sent on request.

VICHY CÉLESTINS

THE WORLD'S MOST FAMOUS NATURAL STILL ALKALINE WATER

THE CO_2 FACTOR IN MEDICATION

For INCREASED EFFECTIVENESS BETTER TOLERANCE GREATER PALATABILITY

Aspir-Vess

—Aspirin with alkali in an effervescent tablet.

Effervescence — secures quick absorption, quicker effect, less danger of gastric upset.

Alkalization — acts synergistically with aspirin in the treatment of colds, influenza, rheumatism.

Each tablet of Aspir-Vess contains aspirin 5 gr., sodium bicarbonate 31 gr., citric acid 21 gr.

Bromo-Vess

— triple bromides without the salty taste.

Combines the bromides of potassium 7½ gr., sodium 7½ gr. and ammonium 1 gr. in a refreshing, effervescent drink. The addition of ½ minim Fowler's Solution decreases possibility of bromide rash.

Cinsa-Vess

—well established, antirheumatic therapy in new, more effective form

Provides a combination of cinchophen 5 gr., sodium salicylate 8 gr., colchicine 1/200 gr., sodium bicarbonate 33 gr., citric acid 21 gr.

The final solution is definitely alkaline, which combats the associated acidotic condition usually encountered, and likewise increases tolerance.

EFFERVESCENT PRODUCTS, Inc.

HEMORRHOIDS

WHITEHEAD OPORATION. *Szekely* advises the whitehead operation in certain cases and discusses same.

Calinich reviews 9 whitehead cases operated upon during the past 4 years and finds continence not perfect in some and yet concludes that this operation should be done in severe cases.

INJECTION TREATMENT. *Alley* states that injection with quinine urea hydrochloride is the method of choice but advises against its use during the acute or subacute inflammatory stage. States that only 10% of his cases have the transitory pain or discomfort following its use.

Cardoner discusses non-operative treatment of hemorrhoids.

Vogel describes a syringe for injection treatment with the plunger notched interlocking with a control spring to permit gauging the dose with pharmacologic exactitude to the twentieth of a c.c.

Chène and *Dubarry* advocate the use of 5% quinine urea hydrochloride as injection media and advise this treatment in uncomplicated cases in the vast majority of cases of hemorrhoids treated.

Quigley describes an anoscope with a terminal light for direct visuallization and a slot to admit a 12 cm.-22 gauge needle to permit injection of hemorrhoids under air inflation. The author

REINFORCING THE DIET
of the
CONVALESCENT ULCER PATIENT

The frequency of symptoms of undernutrition in convalescent ulcer patients has prompted several recent studies of the ulcer diet in an attempt to find some means of reinforcing it.

The conclusions drawn from these studies are that (1) while the bland and comparatively fibre-free character of the ulcer diet must be maintained, (2) greater emphasis must be placed on the inclusion in the diet of foods that are rich in their content of minerals and water soluble vitamins.

These conclusions stress the value of Gerber strained vegetables in the ulcer diet. They are uniformly smooth products with a maximum of roughage removed. They are unseasoned. And they are prepared with air excluded, so that the valuable vitamins and minerals are conserved.

Gerber's

Shaker-Cooked Strained Foods
STRAINED TOMATOES, GREEN BEANS, BEETS, CARROTS, PEAS, SPINACH, VEGETABLE SOUP. ALSO, STRAINED PRUNES AND CEREAL.

Professional samples gladly sent you at your request. Also a supply of booklets giving therapeutic-diet recipes to help patients with the "palatability" factor.

GERBER PRODUCTS COMPANY, Dept. 3311, Fremont, Michigan

ACIDOSIS *or* ALKALOSIS?

prescribe KARO

ACIDS galore are normally formed in the body and eliminated—carbonic, lactic, phosphoric and sulphuric. They are almost completely neutralized by base from cells, intercellular fluids and blood plasma. The body fluids thus maintain the normal faint alkalinity of pH 7.4.

But the defensive mechanisms of the body capable of preventing changes in reaction may be deranged in disease with consequent acidosis or alkalosis. Acidosis is associated with hyperpnea, diarrhea, dehydration, anoxemia, circulatory or renal insufficiency; alkalosis with excessive breathing, vomiting

Treatment of acidosis is designed primarily to correct the underlying cause. In most types, fluids and fruit juices with Karo are forced every hour. In cases associated with ketosis (except where it is a disturbance in carbohydrate metabolism, as in diabetes mellitus) 20% dextrose is given intravenously at repeated intervals. In case of diabetes, insulin is given, by some authorities, simultaneously one unit for each gram of dextrose, until the condition is controlled.

CAUSES OF ACIDOSIS

EXCESSIVE ACID FORMATION

Acid	*Disturbance*
Aceto-acetic B-hydroxybutyric	Starvation Cyclic vomiting Diabetes Ketogenic diet
Lactic	Asphyxia Intestinal intoxication Respiratory failure Shock Burns

DEFECTIVE ELIMINATION

Metabolite	*Disease*
Phosphate	Nephritis
Carbonic acid	Emphysema Respiratory obstruction Myocardial failure Narcosis

CAUSES OF ALKALOSIS

EXCESSIVE LOSS OF ACID

CO_2	Hyperventilation Tetany Cerebral lesions (respiratory center) Hysteria Excessive crying
HCl	Vomiting Pyloric stenosis Intestinal obstruction

EXCESSIVE INTAKE OF ALKALI

$NaHCO_3$	in Pyelitis in Nephritis

From Kugelmass' "Clinical Nutrition in Infancy and Childhood" — (Lippincott)

Treatment of alkalosis depends upon the cause. The most common variety in children is that resulting from prolonged vomiting with loss of acid, salt and body water. No food is given by mouth except fluids with Karo, and saline intravenously. If alkalosis is the result of alkali administration in the presence of nephritis with poor kidney excretion of salts, large amounts of fluids with Karo will favor excess base elimination. Alkalosis from excess alkali administration is alleviated by forcing fluids with Karo.

In both acidosis and alkalosis, Karo is a carbohydrate of choice in the emergency of treatment. Karo consists of dextrins, maltose and dextrose (with a small percentage of sucrose added for flavor), not readily fermentable, rapidly absorbed and effectively utilized.

The Use of BILE SALTS is on the increase . . . So is TAUROCOL

claims better exposure and more accurate hemorrhoidal injection at the apices.

DESICCATION METHOD. *G. D. Graham* describes an ambulatory method by desiccating by use of the Oudin coil. Complete local anesthesia is used. The internal hemorrhoids are blanched and the external hemorrhoids are desiccated around their bases to permit intestinal sloughing.

MUCOSAL REDUNDANCY AND HEMORRHOIDS. In another very excellent paper *Daniels* distinguishes between internal hemorrhoids and redundant mucous membrane which he correctly states occurs not only in the hemorrhoidal zone but frequently may rise high into the ampulla. The author by means of a long proctoscope injects high into this area. He also combines ligature operation with injection in correcting internal hemorrhoids.

Riddoch injects internal hemorrhoids in the presence of fissure after anesthetizing it previously.

Chabreyroux gives vaccine treatment locally or vaginally for hemorrhoids.

NEUROLOGICAL AND INFECTIOUS ANORECTAL SYNDROMES

Huard presents a very interesting and excellent paper on the various anorectal disorders following or associated with *dysentery*, particularly that of amebiasis. Cutaneous perineal amebiasis he states is probably fairly common but difficult to diagnose. Hemorrhoids, perianal abscess, fistula, stricture and prolapse following dysentery are discussed from a surgical point of view. Cancer may be simulated by, may simulate, or may be associated with the dysentery.

Smiley cites a case of fistula-in-ano associated with sciatica which was *cured by fistulectomy.*

Thaysen reports 3 cases of proctalgia fugax and cites others where a syndrome of periodic transient, spasmodic, and frequently violent anal and rectal pain not accompanied by reflex symptoms or anal spasm occurs. He believes

THE VISE-LIKE GRIP

of muscular spasm is relaxed by

*SYNTROPAN

Morphine often *increases* contractions. Ockerblad and Carlson, for example, found that morphine increased peristalsis in the human ureter. Patients with ureteral colic had renewed spasms of pain—worse than before—after morphine. (*South. Med. Jour.*, 29:2, 166).

Syntropan does not depress the pain centers in the cortex. It acts at the seat of the trouble; it overcomes the spasm, provides real relaxation.

Prescribe Syntropan in all spastic conditions, such as gastro-spasm, nocturnal enterospasm, vesical and urethral spasm, dysmenorrhea, spastic colon, and spasms in the respiratory and circulatory systems.

PACKAGES: Oral tablets, in aluminum tubes containing twenty 50-milligram tablets. Ampuls in packages of six 1-cc ampuls, each containing 10 milligrams.

DOSAGE: For oral administration, 1 tablet (50 milligrams) 3 or 4 times a day, or as required. For parenteral administration, ampuls (1 cc = 10 milligrams) 3 times a day, or as required.

*3-diethyl-amino-2, 2-dimethyl-propanol ester of tropic acid.

PROLAPSE

Huet reports a case of fixation of the colon to the broad ligament of the uterus combined with a uterosacral fixation for prolapse.

Mühling describes the injection of 70% alcohol for the correction of anal and rectal prolapse, the protein precipitation, dehydrating and cauterizing effect being responsible for the result gained.

Schmidt describes an original operative method which he terms "gynecologic" inasmuch as similar to perineorrhapy, *a triangular piece of anorectal segment on the* sacral side is excised and the lateral walls are united with deep silk sutures.

F. C. Smith distinguishes between prolapse and procidential according to the Martin classification.

In the DIET During PREGNANCY and LACTATION

HORLICK'S
THE ORIGINAL MALTED MILK

is of much value during the period of pregnancy and lactation, as an aid not only in maintaining the mother's strength and energy, but also in helping to build strong bones and teeth in the developing child. It offers a simple way of increasing the calorie intake; providing extra proteins, carbohydrates, vitamins A, B, D and G and minerals, especially calcium, phosphorus and iron.

Used as a luncheon between meals, or as a table beverage, and taken hot before retiring, "Horlick's" offers readily assimilated, abundant nourishment. It is simply prepared with water only, either hot or cold, or milk may be added when desired. A heaping tablespoonful added to a glass of plain milk, doubles the nutritive energy value of the drink.

In case there is insufficient breast milk, Horlick's Malted Milk supplies a satisfactory supplement in connection with the breast feeding.

On account of their delicious flavor, Horlick's Malted Milk Tablets often appeal when other foods are inacceptable. The Tablets, to be dissolved in the mouth, possess the same remarkably nourishing and digestible qualities as the powder form. They are convenient to carry while motoring or traveling.

Horlick's Malted Milk Corporation
Racine, Wisconsin

Dr. Ely Joins Stearns Staff

Frederick Stearns & Company announce the appointment of Lloyd L. Ely, M.D., as medical director.

The addition of Dr. Ely to the scientific staff of this well known pharmaceutical house is a definite step in the research and professional expansion which Mr. Frederick S. Stearns has been fostering for the past several years.

Dr. Ely is a graduate of the State University of Iowa, and after his interneship acquired some valuable clinical experience with Dr. Frank Smithies, famous Chicago internist and gastroenterologist.

In addition to his private practice in Chicago, Dr. Ely also held teaching appointments at the medical schools of Illinois and Loyola.

Always interested in diabetes and in the development of useful therapeutic agents, Dr. Ely in 1926 joined the Lilly medical staff, where in 1931 he became director of the Department of Medical Therapeutics. His acute interest in diabetes and the recent advances by Frederick Stearns & Company in the development of more promising forms of insulin led him to join the staff of the latter organization.

Dr. Ely has a wide acquaintance with clinical investigators and his association with Frederick Stearns & Company is especially significant at this time, because of the intense research activities being carried on in the Stearns Scientific Laboratories.

Dr. Ely has been a member of the Chicago and Indianapolis Medical Societies, the Illinois and Indiana State Medical Associations, the American Medical Association and the Society for the Study of Internal Secretions.

VITAMINS IN CANNED FOODS

V. VITAMIN G

By 1925, it was apparent that the anti-neuritic vitamin B of earlier investigators was in reality a combination of several vitamins. In that year, Goldberger postulated the existence of a second vitamin associated with the so-called vitamin B "complex" which he designated as the P-P or pellagra-preventive factor. Evidence has been offered that this factor—subsequently named vitamin G—exerts a specific action in the cure and prevention of human pellagra and a similar condition in experimental animals (1).

Since Goldberger's pronouncement, considerable research has been devoted to resolution of the vitamin B complex and, what is equally important, to testing the specificity of vitamin G in the cure of human pellagra (2).

The findings in the laboratory and clinic have not, in some respects, been entirely in accord (3).

As reports of further investigations appeared in the literature, it became clear that the vitamin B complex had been aptly named. At one time claims were made for the existence of as many as eight factors in this complex (4).

While later work has reduced this number, we know today that what has been considered in the past as vitamin G is, in reality, a combination of several factors. A relation between experimental cataract and vitamin G has been described and, recently, another associated factor was postulated (5).

The significance of these individual factors in human nutrition has not as yet been established. However, regardless of this fact, students of nutrition are agreed that we must provide for the inclusion of so-called vitamin G—admittedly a complex—in the daily dietary. It is also obvious that until more is known about the individual components of the complex, we must continue to depend upon present day bioassay methods to determine the "vitamin G" potencies of foods.

In this connection, many canned foods have been found by comparative studies to retain their original vitamin G potencies as measured by methods now in common use (6).

Investigators in the U. S. Public Health Service have described their values in the control of human pellagra (7).

Commercially canned foods, therefore, may be used with confidence that they will supply amounts of vitamin G consistent with the amounts present in the raw food materials.

The Seal of Acceptance denotes that the statements in this advertisement are acceptable to the Council on Foods of the American Medical Association.

Exicol Background

The therapeutic effect of Exicol has been adequately demonstrated not only clinically, but in the laboratory as well. This sound, scientific background is your assurance of effectual results in prescribing Exicol in the treatment of diseases of the biliary tract.

ACTION: 1. Stimulates Gall Bladder evacuation (*Cholagogue*)
2. Increases bile flow from the liver (*Choleretic*)

Indicated in:
1. Chronic Cholecystitis
2. Cholelithiasis
3. Catarrhal Jaundice
4. Hepatitis and functional hepato—biliary disorders.

Dosage: 2 capsules, t.i.d., ½ hour before meals with liberal quantities of water.

Available, in elastic soluble capsules, boxes of 36 and 100

Brooklyn Scientific Products Company, Inc.
70 Fifth Avenue New York, N. Y.

CROOKES KAO-LACTOS B

Protects, Supports, Stimulates

IN GASTRO-INTESTINAL DYSFUNCTION

Removal of toxic elements and protection of irritated mucosae; correction of intestinal flora and elevation of body resistance; stimulation of appetite and intestinal tonicity —these are the keys to the correction of gastro-intestinal dysfunction by Crookes KAO-LACTOS B. Crookes KAO-LACTOS B (in 4 oz. Rx bottles) is indicated in alimentary intoxications, acute or chronic gastritis, fermentation, mild constipation, anorexia and diminished intestinal tone. Crookes Collosol Kaolin (plain or with phenolphthalein), for internal use or as an external dressing for fistulae, is also available, in 6 or 16 ounce packages.

"When it comes to Colloids, call for Crookes".

Authoritative Digest of Scientific Literature on the Banana

"Nutritive and Therapeutic Values of the Banana—A Digest of Scientific Literature" is the title of a new publication offered to you free on request. It has been prepared with the object of enabling the busy physician, as well as the dietitian, to become quickly yet thoroughly acquainted with the published facts regarding the nutritive and therapeutic values of the banana.

This digest, in the form of an annotated bibliography, embraces both articles and books, including English translations of literature originally published in other languages.

You may secure a copy without cost or obligation. Simply fill in and mail the coupon below.

In Peptic Ulcer Therapy

A Successful Combination Treatment

Gastro-enterologists are finding the KAO-MUCIN - HYCOLA combination treatment eminently effective in the treatment of peptic ulcers and colonic disorders.

KAO-MUCIN and HYCOLA should be used alternately; KAO-MUCIN between meals to reduce bacteria, toxins and gas, and provide a viscous protective covering over the ulcerated area; HYCOLA after feedings to reduce excess acidity by colloidal adsorption. KAO-MUCIN assists the therapeutic action of HYCOLA.

KAO-MUCIN-C.P.Co.
Concentrated Vegetable Mucinoid

Relieves gastric pain promptly and allays patient's mental distress. Provides a viscous protective coating over the gastro-intestinal mucosa. Also valuable in colitis, dysentery and flatulence. Supplied in packages of 100 tablets.

HYCOLA-C.P. Co.
Colloidal Aluminum Hydroxide

The colloidal properties of moist aluminum hydroxide in tablet form. Removes excess acidity not by chemical neutralization but by colloidal *ad*sorption. One tablet will adsorb app. 5 cc. of N/10 HCl. Supplied in packages of 60 and 250 tablets.

The Columbus Pharmacal Co., Columbus, Ohio.

BILE SALTS

Fairchild

The sodium glycocholate and taurocholate, the salts of conjugated colic acids in their native association as separated from fresh ox gall.

A stable dry powder; uniform in composition; efficient for the well known therapeutic uses of ox-gall—in disorders due to faulty bile functioning.

Bile Salts preferably to be dispensed in capsule by itself, or in combinations in powder.

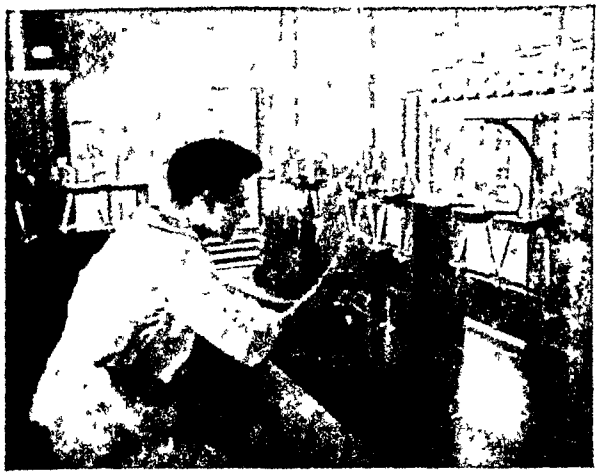
Offered in powder, ¼ oz., 1 oz. vials; in capsules, each three grains Bile Salts.

Fairchild Bros. & Foster
New York

It Flushes the ENTIRE Biliary Drainage System

Without Undue Purgings

Decholin augments the production of bile by the liver cells 100-200%, thereby flushing the *entire biliary drainage system from the smallest* bile channels to the ductus choledochus and gall bladder. . . . *Decholin is a single chemical entity*, no cathartics are added. It acts directly upon the liver parenchyma, and it does not produce undesirable purgings. Decholin is of accepted value in chronic cholecystitis, cholangitis, hepatitis of toxic origin and functional hepatic insufficiency.



Riedel-de Haen, Inc.

COD LIVER OIL

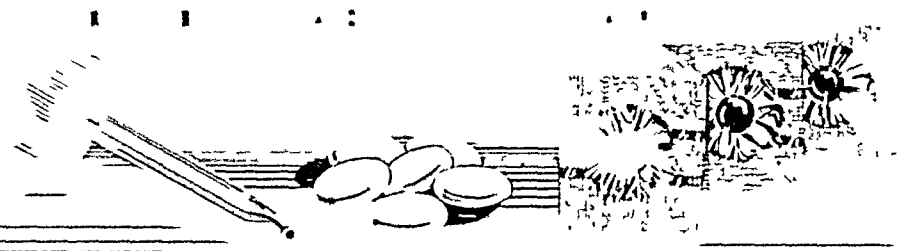
Freed From Its "Excess Baggage"

A contribution of Chemistry to Medicine was the splitting off of the vitamin fraction of cod liver oil from the fatty bulk, the hard-to-digest excess baggage.

This scientific achievement brings to your practice the valuable "A" and "D" vitamins—the "active principles"—of cod liver oil in a concentrate, 100 times the potency of plain cod liver oil* and in dosage forms which are convenient, palatable, economical.

No matter what may be the type of patient there is a suitable dosage form to meet the clinical requirements.

Thus *for the infant* there is White's Cod Liver Oil Concentrate Liquid—only two drops are equivalent to a teaspoonful of plain oil (not a substitute but the natural oil free from its hard-to-digest ballast).



For the growing child and the adult there are White's Cod Liver Oil Concentrate Tablets—each candy-like tablet equals one teaspoonful of cod liver oil *

For those who need cod liver oil in reinforced dosage there are White's Cod Liver Oil Concentrate Capsules—each capsule equals four and one-half teaspoonfuls of cod liver oil.*

The convenience, economy and clinical acceptance of White's Cod Liver Oil Concentrate are attested by the constantly increasing prescription demand for all three dosage forms.

*U.S P. Minimum Standard

White's

COD LIVER OIL
CONCENTRATE

WHITE LABORATORIES, Incorporated - 113 North 13th Street, Newark, N.

"... we know that in the infant and growing child alkali in excess of acid must be stored."

Growth and Development of the Child, Part III, White House Conference on Child Health and Protection, New York, 1932, p. 213.

BUT— many diets are acid-forming

AS pointed out in the Journal of the American Medical Association (Queries and Minor Notes, 103:701, 1934), "... most high carbohydrate foods of the artificial and refined types are lacking in the basic elements. These basic ions, such as sodium, potassium, and calcium, are necessary for the neutralization and excretion of the various acid waste products of the body. Hence carbohydrates may be implicated in the occurrence of such an acid state by displacing other necessary food products from the dietary."

Ordinary cereals and cereal products, meat, and eggs—all produce an acid ash when burned in the body, yet they form the mainstay of the average diet. Although this preponderance of acid-forming foods is not definitely known to have great significance for the health of normal adults, a number of authorities advocate a basic or alkali-forming diet for children and pregnant women.

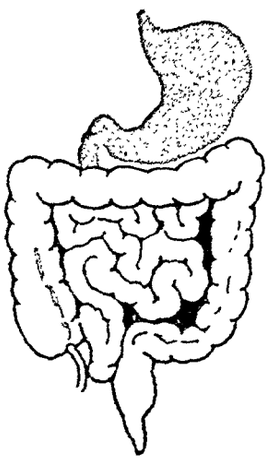
INFANCY AND CHILDHOOD. "Alkaline diets are essential for infancy where growth is rapid," declares Shohl. He calculates the need as 10 cc. excess of 0.1 normal base per kilo per day.[1] Babies fed on breast milk stored an excess of base over acid, the range being from 31 to 56 cc. 0.1 N base per day, is the finding of the Committee on Growth and Development of the White House Conference on Child Health.[2] Lippard and Marples observed greater increases in weight of infants receiving basic diets as compared with controls on acid-forming feedings.[3]

PREGNANCY AND LACTATION. Shohl states, "Pregnancy and lactation require additional alkali—a minimum of 150 cc. 0.1 N base per day."[1] Coons and associates, from acid-base balances taken upon normal pregnant women receiving basic diets, determined that the storage of basic substances was even greater than estimated by Shohl. "This may be some indication," they say, "of the magnitude of the maternal needs exclusive of fetus."[4]

As the chief alkali-forming foods are fruits, vegetables, and milk, the ordinary basic diet consisting of these foods is likely to be low in calories and often does not appease hunger. But Pablum—the only base-forming cereal*—offers a way to add muffins, cereal, puddings and similar "filling" foods to the usual basic diet. Pablum, moreover, is richer than ordinary cereals in calcium, phosphorus, iron, and copper and supplies vitamins A, B, and G.

[1-4] *Bibliography on request.* *Mead's Cereal (Pablum in uncooked form) is also base-forming.

MEAD JOHNSON & COMPANY, - - - Evansville, Indiana, U.S.A.



Pablum (Mead's Cereal thoroughly precooked) is a palatable basic cereal consisting of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa leaf, beef bone, brewers' yeast, iron salt and sodium chloride.

Cereal	Base	Acid
PABLUM	1.8	
Farina		11.0
Oatmeal		12.9
Wheat, whole		11.5
Cornmeal		5.3
Barley		10.1
Rice		8.1

Figures given in the above table are based on 100 grams of food and represent cubic centimeters of normal acid or base.

TESTAGAR for BULK

More and more physicians are finding in TESTAGAR a valuable aid wherever BULK is indicated in gastro-intestinal disturbances.

TESTAGAR is *non-irritating* and meets all requirements in the treatment of functional chronic constipation, where a bulky lubricating substance is indicated.

TESTAGAR is a compound of the husks of Plantago Loeflingii Linn combined with the finest quality of AGAR-AGAR.

The Testagar Laboratories will be honored to receive your request for clinical test samples and further information.

SECTION I—*Clinical Medicine: Diseases of Digestion*

Pyrexia in Gastric Carcinoma*

By

HARRY A. SINGER, M.D.†

and

FREDERICK STEIGMANN, M.D.‡

CHICAGO, ILLINOIS

FEVER as a symptom of carcinoma of the stomach is at present accorded little attention in treatises on gastric malignancy. Although stressed by the earlier writers since Wunderlich (1) in 1856 described the occurrence of pyrexia in malignancy, the modern authors of texts attach very little clinical importance to the presence of fever in carcinoma. Some authors speak of pyrexia in gastric cancer but give the subject merely fleeting consideration (Crohn (2), Smithies (3), Einhorn (4), Riegel (5), Nothnagel (6), etc.), whereas others fail even to mention fever in carcinoma of the stomach (Aaron (7), Cheney (8), Boas (9), etc.). The reasons for relegating the symptom of fever to a position of little or no import are quite apparent. Many writers including a number of authorities on the subject (Kemp 10), Eichhorst (11), Hemmeter (12), Gordon (13) consider fever in gastric carcinoma too uncommon to merit serious consideration from the diagnostic standpoint. Others (Bassler (14), Einhorn (4) take the position that fever, when it does appear, manifests itself too late in the course of illness to be of value to the clinician.

Considering the fact that fever is hardly mentioned by most authors, one is surprised to learn how very common it is when a statistical study is actually made. Fenwick (15) observed pyrexia in one-third of his patients with gastric carcinoma. Freudweiler (16) obtained an incidence of 26% and Friedenwald (17) reported fever in 43% of his series of stomach cancers. Osler (18) makes the statement that fever occurs in from one-half to two-thirds of all cases of carcinoma of the stomach! In the last 1000 cases of gastric malignancy treated at the Cook County Hospital the incidence of pyrexia of substantial degree was found to be 35%. The above statistics should be sufficient to establish the fact that pyrexia is common in cases of neoplasm of the stomach. The current impression that fever appears late is generally but by no means invariably true. As a matter of fact, pyrexia may be the very earliest clinical manifestation of a gastric growth and at times even the only one, the discovery of the tumor being a revelation of the postmortem table. It is this phase of the subject, viz., the occurrence of pyrexia as an initial clinical symptom or sign of carcinoma of the stomach that we wish to discuss and emphasize. Obviously, neoplasms arising in other organs or structures may announce their presence by fever but not nearly so frequently as in gastric growths. Alt and Barker (19) in a follow-up study of 100 cases of fever of unknown origin found that a number died of malignancy and of lymphoblastoma. Kintner and Rowntree (20) made similar observations.

Fever as a symptom of gastric carcinoma is of two types, (1) irregularly intermittent or remittent fever giving rise to the clinical picture of a septicemia of unknown origin (2) more or less regularly intermittent fever associated with chills and sweats, simulating malaria. The greatest number of cases reported in which pyrexia was the initial symptom of a gastric cancer, belong to the septicemic group with only a small number (five) exhibiting the malarial type of paroxysms. The series of cases with the clinical picture of septicemia include the following instances: Archard (21) saw a patient in whom the only symptoms of a malignant growth of the stomach were fever, rheumatic complaints, and edema of the lower extremities. Bassler (14) observed a patient who entered the hospital because of the presence of fever of undetermined origin. In the course of a complete study, a gastric malignancy was found to be the only apparent cause of the pyrexia. Eusterman and Wilbur (22) describe a patient who consulted the Mayo Clinic because of septic temperature, cough, epistaxis and cervical adenopathy. This clinical picture, together with the discovery of ulceration in the mouth, led to the diagnosis of acute septic leukemia. The necropsy, however, disclosed a malignant growth of the stomach which had metastasized to the cervical lymphnodes and brain. Freudweiler (16) reports on two patients who entered the hospital because of fever of obscure origin and who later, while under observation, developed symptoms of malignant disease of the stomach. Kratschmer (23) studied for six weeks a young soldier who presented the picture of a mild sepsis with a soft, systolic apical murmur and a questionably palpable spleen. The correct diagnosis was not made until the patient died, when necropsy disclosed a

*From the Department of Medicine of the Cook County Hospital.
†Late Associate Professor in Medicine, University of Illinois, College of Medicine and Attending Physician, Cook County Hospital.
Dr. Singer died Aug. 21, 1936. His death removes from the ranks of American Gastro-enterologists not only an erudite and charming individual, a great clinician and teacher, but one who gave promise of advancing to the very front rank in his chosen field. *Editor.*
‡Instructor in Medicine, University of Illinois, College of Medicine and Associate Attending Physician, Cook County Hospital.
Submitted August 21, 1936.

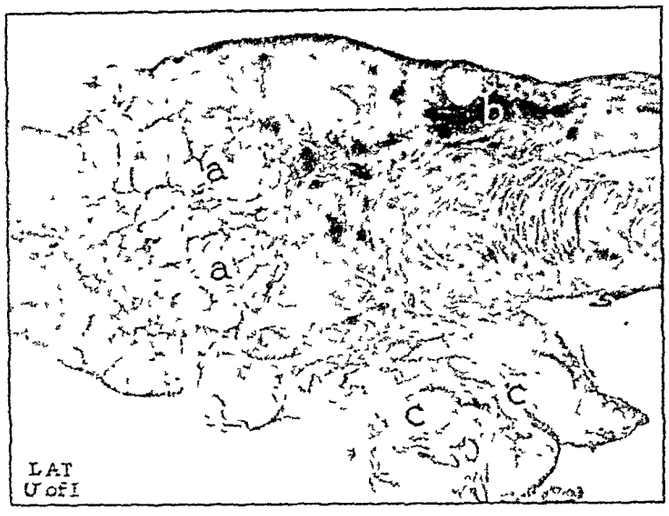

Fig. 1. Small, colloid, carcinoma of the stomach, the first clinical manifestation of which was acute suppurative peritonitis which proved fatal. Almost the entire carcinoma is included in the photomicrograph. The light spaces (a) represent colloid material formed by the malignant cells which are not visible with low power. The dark areas (b) consist of dense accumulations of polymorphonuclear and round cells. Infiltrated omentum (c) is attached to the serosa. No gross evidence of infection of the tumor was detected at autopsy. Magnif. x 4.

carcinoma of the cardia of the stomach with metastases to the pancreas and adrenals.

Of especial interest from the standpoint of fever in the symptomatology of gastric malignancy is Masselot's (24) patient who for twenty-six months before she died suffered periodically from septic manifestations. Various agglutination and other tests failed to uncover the cause of her sepsis. The idea of fever being produced by a silent neoplasm was so foreign that when an X-ray examination disclosed a defect of the pylorus, a gastric neoplasm was not seriously considered. Later, however, when symptoms of gastric disease became obtrusive a laparotomy was performed and an inoperable tumor of the pylorus found. In this case mild gastric symptoms did not appear until a few months before the exitus. Portis (25) presented a male patient of forty-six years, who entered the hospital because of chills, fever, loss of weight and pain in the lumbar region in whom a gastric neoplasm with osteolytic metastases to the spine were found. Septicemia resembling that of typhoid fever was the main symptom in Rhea's (26) patient with carcinoma of the stomach, while in Singer and Shabat's (27) case the abdominal complaints were almost completely overshadowed by manifestations referable to a metastatic suppurative arthritis of the lower spine. Sepsis associated with alternating constipation and diarrhea was the only manifestation of a gastric carcinoma which had perforated into the transverse colon in a patient observed by Starkey-Smith (28). In our present series of four cases reported in detail below the fever which initiated the symptomatology was septicemic in three.

In spite of the fact that malarial-like paroxysms are described in connection with malignancy of the stomach by nearly all authors who discuss at length the subject of fever in gastric carcinoma very few illustrative cases have been described. Hampeln (29) in 1888 recorded in two patients recurrent attacks of chills, fever and sweats which persisted for several months, while gastric complaints appeared only several weeks before death. In each patient a malignant growth of the stomach was found at autopsy. Two other instances are reported by Rovsing (30). One of the patients had malarial-like paroxysms for nearly four years, before a carcinoma of the pylorus was discovered during the course of a complete examination. Resection of the tumor led to full recovery. The other patient manifested chills, fever and sweats for four and one-half months before gastric symptoms appeared. The latter led to the diagnosis of carcinoma of the stomach and subsequent resection with restoration of health. A fifth case reported by Singer and Shabat (27) was that of an ex-sailor who because of chills, fever and sweats was thought to be suffering from malaria. The autopsy disclosed a suppurative arthritis of the lumbar spine with bilateral psoas abscesses. An ulcerating, medullary carcinoma of the stomach located in a silent area (greater curvature, mid-portion) was the only primary site of infection found to account for the purulent arthritis. In only one of the four patients in the present series in whom fever was the first clinical manifestation of gastric malignancy was the pyrexia associated with chills and fever of the malarial type.

The first two patients in the foregoing series will be reported in detail. To conserve space only the bare essentials in connection with cases 3 and 4 will be mentioned.

AUTHORS' CASE REPORTS

Case 1. H. G., a white man of 56, entered the Cook County Hospital, May 29, 1933, because of fever and weakness. According to the history the fever which began several weeks before admission was present daily but did not require the patient to take to bed. Two weeks previous to entrance following the exertion of cranking his car the patient experienced pain in the lumbar region. The backache continued and was present at the time of admission when a substernal pain was also mentioned. There were no other complaints. The patient enjoyed a good appetite, and was free from epigastric pain, nausea and vomiting. At no time was there any digestive disturbance. The remainder of the history was essentially negative.

Physical examination disclosed a well developed and well nourished white male, not acutely ill, but apparently febrile. The temperature by mouth was 102° F., the pulse rate was 110 and the respiratory rate was 28. The systolic blood pressure was 130 mm. and the diastolic 80 mm. The head, neck and lung fields were found to be normal. Soft systolic murmurs were heard at the apex and at the base of the heart. The liver was felt two fingers breadth below the right costal margin. The spleen was not palpated. No epigastric mass was discovered. The back appeared essentially negative except for tenderness on percussion over the lumbo-sacral regions. No other changes of note were present. The Wassermann was negative, the blood chemistry within normal limits, and the urine essentially normal. A roentgenogram of the chest showed a slight infiltration in the base of the right lung.

The patient, feeling quite improved with reference to his back insisted upon leaving the hospital on June 6, 1933, but returned eight days later. During his *second stay in the hospital* the physical signs were essentially the same as those observed at the time of the first admission. The temperature varied generally from 98° to 102° F., but rose occasionally to reach 103° F. The pulse rate was rather rapid. The urine was again reported normal. The hemoglobin was found to be 57%, the erythrocyte count was 3,250,000, the white blood count 9,400 of which 72% were polymorphonuclear leucocytes, 22% lymphocytes, 4% eosinophiles, and 2% monocytes. An electrocardiogram was negative. An X-ray of the spine showed only slight

Fig. 2. An example of infection in another colloid carcinoma of the stomach which ran a febrile course. The deeper layers of the gastric wall are invaded by mucus-producing malignant glands which appear light. In association with the neoplastic elements and extending beyond them are accumulations of cells of an inflammatory nature which stain dark. Magnif. x 33.

osteoarthritic changes in the lumbar region. The Widal test was negative, as was also the agglutination test with *B. melitensis*. A blood culture taken on June 21, 1933, yielded a pure growth of streptococcus viridans. On June 26, the spleen was found to be palpable. In view of the septic temperature, general malaise, palpable spleen and positive blood culture, the diagnosis of subacute bacterial endocarditis was made. The patient again left the Cook County Hospital to enter a private institution.

From the records of the latter it is learned that the patient entered there on June 29, 1933, with similar complaints and practically identical physical and laboratory observations. At this hospital the patient's blood culture yielded again gram positive cocci. The patient was given several blood transfusions in the following four weeks without producing any apparent improvement. He continued to run a septic course and died about five weeks after entrance there with the *ante-mortem diagnosis* of subacute bacterial endocarditis.

The *necropsy* performed a few hours after death disclosed the following significant changes. Along the posterior wall of the distal third of the stomach near the greater curvature was a diffuse, infiltrative lesion. The mucosal surface was a fungating one with many of the areas heaped up into nodular masses. The mucosa was superficially ulcerated, the wall of the involved portion markedly thickened and firm. Many of the nodular areas were seen extending along the mucosal surface of the proximal one-third of the duodenum. Here, however, no ulcerations were present and the nodular areas were more discrete. Along the anterior wall of the stomach, immediately proximal to the fungating growth, the mucosa was thickened. The liver had numerous metastases and weighed 4,375 grams. The spleen was enlarged, weighed 625 grams and had several metastatic nodules. Metastases were found also in the retroperitoneal and mesenteric lymph glands and in the omentum. The heart was essentially normal; its weight being 260 grams. The right upper pulmonary lobe showed a slightly calcified area. The *anatomical diagnosis* was: Adenocarcinoma of the stomach with secondary ulceration; metastatic carcinoma of the lymph nodes, omentum, liver and spleen; old fibrous tuberculosis; cachexia.

Case 2. M. B., a Turkish woman of 51 years of age was admitted to the Cook County Hospital, November 13, 1929, with the following history which was obtained from her son. About one year prior to entrance, the patient noted an irregular fever and weakness. Later in the course of her illness pain in the left side of the upper abdomen appeared. She entered a private hospital where X-rays were taken, but no diagnosis was made prior to her being discharged. No barium meal was administered. Her symptoms continued unabated and the patient grew progressively weaker. Five months prior to admission to the Cook County Hospital the patient developed a severe cough which was productive of a large amount of foul-smelling greenish sputum. This prompted her again to seek medical aid. This time she entered a hospital in connection with a medical school where many tests were performed and many X-rays taken. The patient remained there for six weeks and because of lack of funds was sent to the County Hospital with the diagnosis of undulant fever (positive agglutination in dilutions up to 120) plus lung abscess.

Upon entrance into the Cook County Hospital her complaints were those of vague pains in the left side, fever, weakness, cough and expectoration of a fetid sputum. Her past history was essentially negative except for a "fever" which she had while in Turkey many years prior.

The *physical examination* revealed marked emaciation and pallor. In the left upper quadrant there were tenderness and a sense of resistance as from a mass. An X-ray of the chest was reported as negative. The blood serum gave an agglutination of only 1:80 with *B. abortus* and 1:160 with *B. melitensis*.

The *diagnosis* made by the junior interne, Dr. Melvin Afremow, was pulmonary abscess caused by a malignancy of the stomach with abscess formation and rupture through the diaphragm. The patient grew rapidly worse, and died the third day after entrance before any further studies including X-ray of the stomach could be completed.

The *necropsy* was performed several hours after death by Dr. R. H. Jaffé from whose description the following relevant excerpts were taken. 'The basal portion of the left lung in its medial half is loosely adherent to the diaphragm. Near the anterior aspect of the diaphragmatic surface of the left lower lobe the pleura and diaphragm are defective and a superficial excavation of lung parenchyma is found 5 cm. in diameter and 1 cm. deep, lined by a well-defined membrane 1 mm. in thickness. On the anterior surface of the fundus of the stomach, beginning just below the cardia and extending from the lesser to the greater curvature, is a large mucosal defect nine and one-half cm. in diameter. This mucosal defect leads into a large, supragastric cavity. The wall of this cavity is made up of the liver, and the upper pole of the spleen. The cavity is lined by soft, friable, and firmer cauliflower masses. The sectioned surface of the wall is diffusely white and opaque. The remainder of the gastric mucosa is smooth and covered by blood tinged mucus. The perigastric and peripancreatic lymph nodes are enlarged up to 3 cm. in diameter, firm, smooth and white."

The *complete anatomical diagnosis reads:* "Fungating medullary carcinoma of the anterior wall of the stomach with formation of a large perigastric cavity compressing the liver, extending through the diaphragm and into the left lower pulmonary lobe; metastases to the peripancreatic and perigastric lymph nodes; focal, fibrinous adhesions between the base of the left lower pulmonary lobe and the diaphragm; erosion abscess of the left lower pulmonary lobe; severe brown atrophy of the myocardium,

passive hyperemia and edema of the lungs with compensatory emphysema of the anterior portions; anemia and fatty changes of the liver; fibrosis and slight inflammatory softening of the spleen; anemia and arterio-sclerosis of the kidneys; bloody intestinal and gastric content; senile involution of the internal genitalia; edema of both lower extremities and of the labia majora; advanced emaciation."

Case 3. G. B., a white male of 63, experienced a continuous, low-grade fever unaccompanied by any local symptoms. He had been treated for a grippal infection by his local physician in Gilman, Ill., without any apparent improvement. He consulted Dr. Adolph Kraft of Chicago, who referred the patient to one of us. (H.A.S.). The initial examination in October, 1930, yielded no significant diagnostic information. The patient who had not planned to stay in the city agreed to return to Chicago in a short time for observation and study. He did not return however, until six months later at which time the additional symptom of sharp, knife-like pain felt in the region of the left shoulder, and synchronous with respiration was elicited. No physical signs of pleuritis or other chest pathology were obtained.

On the basis of the history of fever of obscure origin and indications of irritation of the diaphragm probably from the peritoneal side a *diagnosis* of carcinoma of the cardiac portion of the stomach with secondary infection was made. An X-ray of the stomach with the aid of a barium meal disclosed an extensive filling defect involving the proximal end of the stomach.

After a lapse of a few weeks, digestive disturbances consisting of belching, bloating, and epigastric heaviness appeared. The shoulder pain became associated with chest pain which overshadowed the dyspepsia and caused considerable suffering. The fever persisted while loss of weight and strength was becoming quite apparent. The patient grew progressively worse and died at home eight months after the appearance of local symptoms and sixteen months after the onset of fever. No autopsy was performed.

Case 4. F. S., a white male of 54, a gardener by occupation, was in the habit of spending his annual vacation during the winter in the southern part of the country. In 1934, he chose to spend his holidays in Hot Springs, Ark. He felt quite well during his vacation but soon after returning to his home in Oak Park, Ill., early in February, 1935, he experienced chilliness, feverishness and general weakness. He consulted his family physician who diagnosed "flu" and advised him to remain in bed. At the end of two weeks instead of recovering, paroxysms of chills, fever and sweats occurred. The family physician was again summoned and ascribed the illness to malaria and administered quinine. Following ten days of quinine therapy the paroxysms became less frequent and the patient felt somewhat improved. The improvement, however, was only of limited duration, for chills, fever and sweats returned with increased frequency and intensity. Up until June 15, 1934, the patient had had no specific complaint referable to the gastro-intestinal tract except perhaps for lack of appetite. The anorexia had been attributed to the fever. On June 15, however, the patient complained of severe upper abdominal pain which rapidly became diffuse and failed to remit even after medication prescribed by his physician. He developed vomiting, distention and obstipation and his general condition grew progressively worse. On June 17, he appealed to one of his employers, Dr. O. C. Nelson, who felt an epigastric mass and recognized the presence of a diffuse peritonitis. Dr. Nelson advised the patient to enter our service at the University Hospital where the patient died the following day.

The *necropsy* disclosed an ulcerating, necrotizing medullary carcinoma of the stomach with perforation through the infected, necrotic portion of the neoplastic tissue and an acute diffuse fibrinopurulent peritonitis. There was no focus of infection in the body other than the infected gastric malignancy.

COMMENT

The causation of fever in gastric malignancy is at present a matter of conjecture. Some authors consider absorption from the tumor the principal factor in the production of pyrexia. Wassiljeff (31), who reviewed the literature up to 1895, arrived at the conclusion that fever in carcinoma may be due to absorption of tumor cell-production from either breaking down (retrograde metamorphosis) or growth and dissemination. Wassiljeff looked upon the fever as an index of the rapidity of the growth and spread of the carcinoma. Gordon (13) twenty-five years later expressed a similar opinion, viz., that fever was due chiefly to rapid growth and multiplication of carcinoma cells and spoke of "growth fever" as contrasted to "complication fever." Hemmeter (12) who considered fever of rare occurrence in gastric carcinoma believed the pyrexia a consequence of autointoxication. Eichhorst (11) was also of this opinion. Alexander (32) spoke also of carcinoma fever independent of suppurative complications as abscess, etc. Other authors emphasized septic complications due to secondary infection of the carcinoma (Finlayson (33), Muller (34), Crohn (2)). Achard (21) listed a number of local, regional and metastatic infectious lesions originating in gastric carcinomas. A third group of authors did not stress any specific etiology in the causation of fever but mentioned both absorption from the carcinoma or its products and secondary infection (Osler (18), Smithies (3), Freudweiler (16), Bassler (14), Kemp (10)).

Our own investigations lead us to doubt that autointoxication furnishes an explanation for the frequent fever in gastric carcinoma. With regard to absorption due to rapid multiplication and dissemination, it is a daily observation that the extent and rapidity of growth of the neoplasm bears no relationship to the presence or absence of fever. We, among others have observed a considerable number of small carcinomas accompanied by fever where the rate of growth was minimal and the extent of spread negligible. The case of Rovsing (30) cited above in which the tumor was strictly localized and resectible after four years of fever speaks strongly against the occurrence of "growth" fever in gastric malignancy. In connection with absorption from breaking down of malignant tissue, however, it is quite conceivable that pyrexia may develop where rapid and continuous destruction of cells occurs. In the use of radiotherapy for the treatment of hyperplastic and neoplastic growths a brief period of pyrexia is a more or less regular consequence. It is hardly likely, though, that spontaneous retrograde metamorphosis even begins to take on the proportions of artificial destruction and if it does so, that extensive cellular degeneration is as prolonged and persistent as is the fever of gastric malignancy. Furthermore, one observes clinically massive tumors with extensive degenerative changes where fever is completely lacking. One is forced to conclude, therefore, that the autointoxication theory was invoked not because of any scientific or clinical evidence but on account of the failure to identify any demonstrable cause of the fever.

A study of post-mortem material lends support to the belief that the fever in gastric carcinoma is in

Fig 3. An ulcerating carcinoma of the stomach associated with septic manifestations. The invading carcinoma cells which are large and deeply stained are found in association with collections of polymorphonuclear leucocytes which are microscopic abscesses. Macroscopic signs of infection were not apparent to the prosector. Magnif. x 50.

general due to infection. If one observes the character of the neoplasm which is so frequently associated with pyrexia he will notice that it is medullary in type and frequently ulcerated. The gross suppurative lesions which complicate gastric carcinoma are too well known to require more than mere mention. They include infection of the tumor itself, bacterial invasion of the gastric wall (phlegmonous gastritis), perigastric abscess, purulent perigastric lymphadenitis, and distant metastatic, suppurative lesions as in the bones and joints. As pointed out elsewhere (see Singer and Shabat (27)) a purulent bone or joint of obscure etiology in a middle-aged or an elderly individual should lead to an investigation for a silent carcinoma in the gastro-intestinal tract and most especially in the stomach

When gross suppuration is absent a careful microscopic study generally discloses a portal of entry in the stomach for bacteria. The ulceration may be inconspicuous and seen only with the aid of the microscope. That pathogenic organisms enter the systemic circulation through the defective area is attested to by the subjacent zone of inflammatory reaction. In most instances the infiltrated polymorphonuclear leucocytes are more or less intact (Figs. 1, 2). In a few cases, however, liquefaction necrosis occurs and minute intramural abscesses develop (Fig. 3). The occurrence of systemic invasion by bacteria in the absence of gross suppuration has been known for many years. Hanot (35) referred to a septicemic form of gastric carcinoma in which positive blood cultures were at times obtained during life. Fromme (36) explained in 1907 that "due to mechanical damage of the carcinoma, large lymph routes are opened and numerous bacteria are introduced into the lymph glands, the barriers of which become overwhelmed." The microscopic demonstration of ulceration surrounded by an inflammatory zone merely offers further evidence to the assumption that the portal of entry is located in the new-growth.

It was, and still is, generally believed that the presence of fever in gastric carcinoma adds greatly to the gravity of the prognosis. This view was fully justified before gastric resection was more or less universally feasible since the sepsis if unchecked frequently produces death before the carcinoma has exerted much influence upon the patient's general health. However, in this day of advanced surgical development the opinion that fever in the words of Einhorn (4) "is always a bad omen" is hardly tenable. The prognosis is dependent chiefly upon the operability of the neoplastic growth since the successful removal of the tumor as in the two cases of Rovsing (30) eliminates the focus of the sepsis. The bulk of the tumors which ulcerate and permit entrance of bacteria into the tissues and lymphatics and thence into the blood stream are soft, polypoid growths which protrude into the gastric cavity. These intralumenal growths are not infrequently attached to the gastric wall by a relatively narrow pedicle and free from extensive metastases. Hence they lend themselves admirably to complete extirpation. The dense, scirrhous carcinomas, which do not tend to ulcerate and become secondarily infected, exert their growth energies in contrast to the medullary tumors toward extension along the wall of the stomach and into the extragastric structures rather than into the lumen. These scirrhous growths are generally unaccompanied by fever but yet are notoriously unfavorable cases from the standpoint of both resection and recurrence. Fever in carcinoma therefore should not be considered an ominous sign for it may lead to early recognition and timely removal of the growth.

SUMMARY AND CONCLUSIONS

The symptom of fever in gastric carcinoma is accorded but little attention in texts and in medical literature. The reasons generally given are twofold. In the first place, pyrexia is considered to be infrequent in occurrence and secondly its appearance takes place too late in the course of illness to be of value for purposes of diagnosis.

Statistical studies indicate that fever is of quite common occurrence for the incidence of pyrexia in gastric malignancy is approximately 35%. Furthermore, attention to clinical histories shows that in a certain (although very small) percentage of cases, fever constitutes the initial and at times the only clinical manifestation of the growth.

Four cases of gastric carcinoma are presented in each of which the initial clinical symptom was fever and its concomitants. The first case was diagnosed clinically as subacute bacterial endocarditis, the second case as undulent fever and lung abscess, the third as malaria, and the fourth was treated for influenza.

The etiology of the fever in gastric carcinoma is in general secondary infection. Where gross ulceration of the growth and apparent suppuration are lacking, careful search almost invariably discloses microscopic defects of the surface of the growth. About these ulcerative sites evidence of marked inflammatory reaction is seen. The zones of inflammation are at times

purulent indicating that bacteria find entrance through these portals to reach the blood stream. The prognosis in gastric cancer is not necessarily rendered ominous by the presence of fever.

In cases of fever of obscure origin occurring in individuals of carcinoma age, roentgen search for a silent malignancy, particularly of the stomach, is indicated.

The Prognosis in Regional Ileitis*

By

BURRILL B. CROHN, M.D.
NEW YORK, NEW YORK

IN the last four years a considerable literature has appeared centering around the subject of inflammatory lesions of the small intestine, particularly the ileum. Undoubtedly the publication of the paper by Crohn, Ginzburg and Oppenheimer (1), in which a clinical and pathological description, as well as a name, was given to the disease, helped to focus medical attention on the susceptibility of this segment of the intestine to inflammatory lesions.

The predilection of the terminal ileum as a focus of granulomatous inflammation was pointed out, and the significance of both external abdominal wall fistulae and internal visceral fistulae was emphasized. In this earlier paper based upon 14 examples of the disease, the low-grade chronic course and benign outlook were predominant; occasional cases with the late feature of small intestinal obstruction due to cicatrization were mentioned, those latter representing attempts at spontaneous healing.

In a later paper (2) it was recognized that this very type of benign inflammatory granuloma could involve the jejunum as well as the ileum, a fact which had already been observed by Harris, Bell and Brunn (3), as well as the occasional familial occurrence of the disease in more than one member of a family. Rarely, combined forms of the disease have been noted (4) in which both ileum and colon have been involved. The true interpretation of this type of extensive ulcerating granuloma is still open to interpretation. True ileitis, terminal ileitis, very rarely involves the colon, though in my experience I am willing to recognize such types of complicated involvement.

Dr. A. A. Berg, who has operated upon a large number of cases, takes a different view, holding that all such cases are instances of disseminated ulcerative colitis with extension into the ileum, essentially "right-sided colitis" with incidental overriding of the ileo-cecal valve and a superficial atypical involvement of the mucosa of the terminal ileum. The last word has not yet been said on this subject. Both views may likely be correct. Suffice it to say at this moment that the success of A. A. Berg in extensively resecting these slowly extending types of "right-sided colitis" has demonstrated the fact that the ileum is almost universally involved in that unusual type of disease.

*From the Medical and Surgical Services of the Mt. Sinai Hospital, New York City.
Read before the Medical Society of New Jersey, June 4, 1936, Atlantic City, N. J.
Submitted July 1, 1936.

The experience of other authors on the topic of ileitis as represented in current medical literature has confirmed our first impressions and has amplified and added some interesting features. Bockus and Lee (5), Mixter (6), Colp (7), Clute (8), Brown, Bargen and Weber (9), Cushway (10), Jackman (11), Powers (12), Green and Pompen (13), Erdmann (14), Felsen (15), Golob (16) among others have all described typical and illustrative examples of this recently recognized pathological process. Probstein and Gruenfeld (17) have urged the acute aspect of regional ileitis; Kantor (18), has described its roentgenological appearance, giving it the apt title of the "string sign." At the German Surgical Congress in 1933 the operative experiences of Fischer, Lührmann, Finsterer and von Haberer were extensively discussed (19). In a recent paper read before the American Gastro-enterological Association, A. A. Berg gave his first extensive report on the surgical treatment by resection of 32 cases of regional ileitis.

That the disease is wide-spread and universal would appear from the extensive literature which has appeared in the medical files. Besides the American publications, which geographically cover the United States and Canada, Great Britain, Germany, Holland and Belgium have already contributed typical examples.

Aside from the suggestion of Felsen (15) that bacillary dysentery plays a role, no suggestions as regards etiology have been advanced.

Just this month Koster (20) has added 17 cases of his own, confirmed by operation. He has also discussed in an interesting way the clinical features and the prognosis of 127 cases culled from the literature and posed some interesting queries.

In a disease the course of which covers usually many years, four years of experience and observation is obviously too short a period to allow of safe deductions regarding the ultimate prognosis and the optimal type of treatment. In its most usual form the disease extends slowly over a period of years with low-grade temperature, mild abdominal cramps, moderate diarrhea and with a slowly progressive loss of weight and an advancing anemia.

But several interesting questions suggest themselves. Among these may be mentioned the following:

1. What is the outlook for cases which have undergone radical resection?
2. Is a palliative surgical procedure, such as a short-circuiting operation warrantable, and what is its ultimate prognosis?
3. What is the proper procedure in the acute type of ileitis?
4. What happens to the case of regional ileitis if no operation is performed?

Final answers to these queries are at this time out of the question; more time, more experience and a more diversified study by various internists and surgeons are prerequisites to definite conclusions.

However, my experience with, to date, 68 personally observed cases, justifies the discussion of these various open issues.

1. *Radical Resection:* It is a pleasure to acknowledge the capable surgical cooperation of Dr. A. A. Berg, who not only operated and resected the very first cases observed at our hospital, but whose recent report on the successful excision of 32 cases represents the greatest surgical familiarity and the widest experience known to us at this date. The type of operation advocated by Berg is a wide resection of the diseased process in the ileum, together with the cecum and ascending colon; an anastomosis between the residual ileum and the proximal transverse colon is established. The extent of resection of the ileum is determined (according to Berg) by the degree and latitude of mesenteric lymphyadenopathy, since the enlarged succulent lymph nodes in the mesentery are the surest guides to the extent of the inflammatory process in the ileum.

Thirty-two cases with one surgical death probably represents the optimum result as judged by the experience of a mature and capable surgeon.

The post-operative functional result is good. The shortened alimentary tract predisposes to intestinal movements which are somewhat greater than normal; 2 to 3 daily defecations are the rule, but cramps and urgency are absent; a great gain of strength and weight and hemoglobin is universal. Recurrences are not reported by this author.

Where long segments of the small intestine are removed, frequent defecations of normal intestinal formation may take place, though these are not associated with recurrences of ileitis. In the course of a few months the stools slowly solidify and form, approaching the semblance of semi-solid defecations.

Fistula formation as a post-operative complication does not appear. Both small and large intestine, in the presence of benign inflammatory processes, seem to tolerate extensive resections with little shock and a very low mortality rate; this in contrast to the high risk of any operative procedure where malignancy exists.

In competent hands, a clean and wide resection of the diseased segment of the ileum seems to constitute the summation of most desired procedures; the type of anastomosis, whether to ascending, transverse or even sigmoid colon, seems to be comparatively immaterial. The operative risk being overcome, the ultimate prognosis in this type of chronic ileitis is excellent.

Perhaps the risk of operation could be reduced by a two-stage operation, doing the anastomosis at the first, and the resection at the second.

2. *The Acute Type of Ileitis:* Cases with acute onset, with a history of less than 4 months, are not infrequent, though besides the rule. In 7 instances the symptoms varied from 2 weeks to 4 months, often with high temperature, vomiting, diarrhea and occasional collapse. It is interesting to note that in 3 of these 7 cases, obstructive symptoms were already present at the time of the operation, indicating that within a few weeks, the entire gamut of inflammation, exhaustion, diarrhea, fistulae formation and stenosis may be run. Obviously, the prognosis is altered by the severity and the rapidity of the course of the disease. Two of these patients died; one of these cases had occurred in 1928 before the nature of the disease was known, no operation being performed. He developed many fistulae to the abdominal wall, to the colon, to the bladder, and to other segments of the ileum, as well as a localized peritoneal mass, all within eight weeks.

The other fatal case followed an attempt at resection, death taking place one week later as a result of exhaustion. Five cases survived resection in the presence of the acute lesion; all have remained well. Pallia-

tive attempts at drainage, or of appendectomy, or of skillful neglect seem useless.

However, in the very recent paper by Koster (20), he has operated upon six cases of acute ileitis in all of which he dropped the involved ileum back into the abdomen without attempting resection. At the time of his writing he reports that the patients are apparently well; there is no statement of the duration of observation since the time of operation. I know of two other cases of acute ileitis which was dropped back into the abdomen several years ago, and which is apparently doing well. I believe the issue is still open as to whether an acute ileitis can spontaneously resolve.

It is obvious that resection, even in the acute phase of the disease can be successfully accomplished without too much risk. On the other hand, the cautious surgeon may exercise good judgment in not attempting resection at this stage. He may well be guided by the subsequent course of the case since spontaneous resolution may be complete, or it may be partial, or the case may immediately face complications, whereupon a second operation, and now a resection, becomes mandatory.

3. *The Prognosis of Palliative Short-Circuiting Procedure:* Many surgeons have attempted to relieve or cure the disease by anastomosing proximal healthy ileum to healthy colon, thus short-circuiting the lesion and rerouting the intestinal content over normal mucosa. Studying the records of 16 such cases, leads to conflicting reactions. In nine of these sixteen cases the anastomotic hook-up failed to cure the disease or alleviate the symptoms. Eventually, radical resection was forced, in 3 instances with fatal issue. On the surface, it would appear that palliation is not only futile, but in addition increase the risk of subsequent operation.

On the other hand, I have, by courtesy of both Dr. Richard Lewisohn and Dr. Ralph Colp, knowledge of 6 cases of ileo-colostomy for extensive and severe instances of ileitis. These cases have all been operated within the last year or two years; most of them seem to be doing well, that is, gaining in weight and strength with disappearance of local masses and subsidence of the severe diarrhea; occasional mild cramps and diarrhea persist in some of the cases.

It is much too soon to try to evaluate the ultimate benefit of such a procedure. That short-circuiting frequently fails, there is no doubt; the study of previously operated cases is testimony to its inefficiency. That it may also at times suffice to cure must remain an open question for the time.

In the article by Koster (20), there is a discussion of the benefits of short-circuiting operations with a review of the immediate results in 15 of such procedures. These cases were culled from among the 127 cases reported in the literature, not all of which are true ileitis. In 13 of these 15 cases the short-circuiting seemed to alleviate the symptoms, a rather promising outlook. However, no follow-up should ever be attempted from an analysis of cases in the medical literature since the publication of a case does not end its life history; recurrences are still conceivable even after supposedly successful and closed cases of sidetracking. It is plausible that shortcircuiting a severe lesion may for the moment benefit the patient causing the disappearance of inflammatory masses and improving the patient's general health. However, the ultimate prognosis is, to my mind, still in doubt.

The risk of a palliative short-circuiting operation is small, the risk of resection somewhat greater. Of the latter, the end-result is almost assured of satisfaction. But if a short-circuiting anastomosis can relieve symptoms and cause great gain of weight, it must be considered as a possible satisfactory operation and be given due time and due consideration before it will achieve its true evaluation as a therapeutic procedure.

4. *Unoperated Cases—The Ultimate Prognosis?* Seventeen cases of ileitis in which no direct operative interference has been practiced are now under observation. The diagnosis has been satisfactorily established and confirmed by clinical means aided by roentgenography, or as in five cases, by exploratory laparotomy. In these latter instances the lesions was accidentally found in the course of an appendectomy or a cholecystectomy. Either unfamliarity with the lesion, or surgical caution, or apparent good judgment dictated a policy of skillful neglect, and the lesion was left undisturbed. Obviously the first question which is posed is, Can ileitis heal itself? Is spontaneous resolution without stenosis possible? Or, failing a natural cure, what is the life history of the process? What is its rapidity of advance, and when do complications (fistulae, perforations, stenosis) occur? Seventeen cases followed for 1 to 3 years cannot afford satisfactory answers to these interesting queries at this early date.

Three of these seventeen cases went on to a fatal termination as determined by autopsy; all died of peritonitis and exhaustion. Another unoperated case had to be resected after two years because of a rapidly downhill course with fever, diarrhea, mass formation and obstruction.

Four of these cases without operation are seemingly doing well, gaining weight slightly, showing an occasional slight tendency to diarrhea, but no real abdominal distress and no loss of efficiency. Considering how often in the anamnesis of cases of regional ileitis we obtain a description of mild pain and diarrhea dating 10 to 15 years back, it is not surprising to note in these few cases an apparent standstill of the process following exploratory laparotomy. I strongly suspect that these cases will eventually form fistulae, a mass, or become obstructed, though it take years for that eventuality.

And yet, scientific precision and clear thinking require one to maintain the premise that a complete restoration ad integrum is within the possibilities of nature.

Another four of these 17 cases (unoperated) are obviously not improving; the symptoms of mild bouts of diarrhea and cramps continue, associated with fluctuating slight loss or slight gain of weight. Of these cases I feel that the "writing on the wall" is clearly legible. The remaining cases are lost to the present follow-up, but will, I hope, because of their value for study, be recaptured.

The problem of treating ileitis by medical palliation can be hardly more than stated; in the fulfilment of time and of study lie the answers. Premature assumption may lead to erroneous conclusions. This eventuality is well illustrated by a recent experience patient who had been explored but not resected, well for two years, so well that he was conside instance of spontaneous cure. Acciden

chance he was discovered in another institution where he had been operated upon in an emergency for small intestinal obstruction, and a segment of diseased terminal ileum resected.

A non-roughage diet seems to benefit ileitis cases. Pain, distress and diarrhea are all relieved when the patient is put on a strict non-roughage diet with pureed vegetables and fruits.

One of my cases of diffuse ileojejunitis was, because of the wide spread process, considered a poor surgical risk. She has lost all her symptoms and gained 25 pounds of weight in a few months, the only form of therapy being the insistence upon the elimination of roughage from her diet. Other cases have similarly shown definite clinical improvement on this form of therapy.

There is no medicinal treatment of this disease.

Since obviously two years of complete normalcy of symptoms can simulate good health, then much more time must elapse before final conclusions can be drawn. Perhaps it will be as with ulcerative colitis: who can say when a case is cured, and who insure against a possible recurrence, no matter how long the freedom from symptoms, except where radical resection has been performed?

5. *Fatal Cases:* In a disease as apparently as benign as regional ileitis, it would be interesting to analyze the deaths that occurred in our experience or are known to have happened in cases whose course has been followed. I know of eight such deaths, three of which occurred without the aid of surgery; five deaths followed attempts at surgical procedures, usually with resections. In the three unoperated cases, death resulted from diffuse or localized forms of peritonitis, the formation of an extensive suppurative mass, or as terminal inanition and exhaustion usual with the formation of multiple fistulae. It is fair to say that had these cases been recognized in time, operation would have had a fair chance of success. Careful watchfulness in the face of a spreading and exhausting process availed not at all.

The post-operative deaths also yield interesting data. One case was resected by a general practitioner who should better have known his own limitations. One was an extensive resection of all of the ileum and much of the jejunum; the case had passed as one of non-tropical sprue for some time; the risk of operation was realized at the moment. Two of the remaining cases were complicated by previous anastomoses and short-circuiting operations. In the eighth case death resulted from post-operative exhaustion complicated by the development of a psychosis of a violent nature. In most of these cases, the fatal issue might have been avoided by earlier operation when the unfavorable trend of the case should have been recognized, and possibly better by a direct attempt at resection rather than palliative surgical procedures. Breaking down the mortality figures, it will be seen that of 17 cases not operated upon, 3 died (17.6%), while of 51 cases operated, 5 died (9.8%). In spite of the extent of the procedure, the risk seems twice as great when surgical aid is refused to the patient.

CONCLUSIONS

There are two good reasons why conclusions should not be drawn from the incomplete facts presented in this paper. For one, the series of cases is too small; for two, the time elapsed is too short to allow for decisions to be made. The disease is a long drawn-out process, its life history will probably be written by the next generation of clinicians, its eventual operative management by future surgeons. In the best of hands the prognosis is excellent when a radical resection is performed. The mortality rate is low, the end-result excellent. Palliative short-circuiting procedures, as well as skillful neglect and so-called conservative medical treatment are still on trial, and the prognosis still to be determined.

On the Possible Relation of Bacillary Dysentery to Non-Specific Ulcerative Colitis*

By

ABRAHAM PENNER, M.D.
NEW YORK, NEW YORK

SINCE its first description by Wilks and Moxon (1) in 1875 and by Hale-White (2) in 1888, "ulcerative colitis" has been a storm center among gastroenterologists. In his original paper, Hale-White presented these cases, which form the first attempt to establish a group of ulcerative lesions of the intestinal tract with the widest possible varieties of etiology, as a new entity. Of his eleven cases probably only two or three would be considered as even fairly typical today. The lesions found at necropsy varied in distribution from jejunum to anus showing the acutest lesions distally as a rule. This author remarks, "It no more follows that because there is ulceration of the intestine which in some specimens reminds one of dysentery that the disease from which the patient died is dysentery, than because a condition of the larynx quite indistinguishable from diptheretic ulceration is found that therefore the disease causing the ulceration is diphtheria."

In this fashion ulcerative colitis has come down to us through the years, passing through repeated phases of recognition as an entity, followed by renewed attempts to include it in other and more thoroughly established categories. These recurrent episodes have centered almost exclusively about attempts to prove a single inclusive etiology for this condition.

A brief and incomplete enumeration would include as sole causative factors: psychogenic, neurologic, unknown toxic, vitamin deficiency, endocrine deficiency, Bargen diplococcus, streptococcus, amoebic infestation, B. Coli infection, mercury or bismuth poisoning, tuberculous, syphilitic or dysentery infection. In recent years, further attempts have been made to prove the dysentery bacillus to be the only factor involved. In the following an attempt will be made to present the evidence as proposed, evaluate it and discuss the difficulties and sources of error in the interpretation of the data presented.

DIAGNOSTIC CRITERIA

(A) Isolation and identification of B. dysenteriae: From the point of view of scientific accuracy the ideal way to prove the dysenteric origin of a case of ulcerative colitis would be the unequivocal demonstration of the presence of a strain of *B. dysenteriae* in the excreta or in the intestinal lesion of the patient. The culture of these organisms from the stool or ulcerations is fraught with difficulties, not only involving the method of obtaining the type of specimen most likely to yield a positive result but also the more detailed and complex technical procedures involved in choosing media, choosing suggestive colonies, subculture, etc.

There is no doubt that the best results are obtained when the original culture material is removed directly from the bases of the ulcerations with the use of the proctoscope or sigmoidoscope for visualization. This has been repeatedly emphasized by Seligman and Cossman (3), Seligman (4), Egan, *et al* (5), Fletcher and Mackinnon (6), Smyly (7), Hern (8), Mackie and Gaillard (9). Lacking the opportunity to do this, one may still have a reasonable chance for success if cultures of the bloody mucus of a freshly passed stool are made.

Having begun in this fashion, we may then justly enquire as to the possibilities of recovering a specific organism at various stages of the disease. In this connection we may refer to the experience of Martin and Williams (10), who, in repeated cultures taken in a series of 1050 cases occurring in connection with acute epidemic dysentery, were able to recover the specific organism in almost 70% of cases in the first week of illness dwindling to less than 10% by the end of the second week. Similar data are contributed by Seligman and Cossman (3) and Seligman (4). In an especially thorough and important study of chronic dysentery, Fletcher and Mackinnon (6) were able to isolate a specific organism in 88 of 229 patients, (38.6%) who had been affected with dysentery from one to thirteen years previously. Four of these cases had been ill thirteen years before the follow-up examination was made and still presented positive stool cultures. In order to obtain these results we note that 13 of the cases were examined 469 times with positive results on 207 occasions, i.e. about 44% of the cultures were positive. In a somewhat smaller series of cases of known chronic dysentery, varying in duration from three months to five years with an average of one and one-quarter years, Smyly (7) was able to recover specific organisms in 50 of 62 cases, i.e. in 80.6% of his series. Similarly, Thorlakson (11) was able to culture *B. dysenteriae* from the lesions of six of his nine cases (80%). Schürer and Wolff (12) likewise were able to recover these organisms in seven out of nine cases of dysentery over six months in durations. It can be seen that, with the improvement in bacteriological technique in recent years, the incidence of recovery of specific organisms has incresaed remarkably in cases which are known to have been Bacillary Dysentery from the onset.

Having placed the isolated material on Endo plates (or, if desired, on Conradi-Drigalski or Teague medium) these are frequently inspected and the pearly grey colonies isolated to the various sugar media for fermentation reactions as well as glucose agar slants in preparation for specific agglutination reactions. At this point we meet with our first major obstacle. This is due to the marked tendency shown by the various members of the dysentery group to differ from time to time in their fermentative abilities. To no less a degree it is due to the similar variability shown by the members of the B. Coli group so that when first isolated the latter may present fermentation reactions identical with those considered typical of the dysentery group. This has been a matter of daily experience in routine stool cultures so that a uniform policy of repeated subculture has been adopted with resultant elimination of this source of error. Apparently Gardner (15) as well as Lentz and Prigge (16) and Egyedi and Kulka (17) have had similar experience.

Even within the dysentery group itself we find such extreme variability in fermentation reactions that these

*From the Medical Services of the Mount Sinai Hospital, New York City.
Submitted July 1, 1936.

cannot be used as the sole mode of identification of members of this group. Subdivisions of the so-called paradysentery group based on the fermentation of saccharose and maltose are frequently given. Thus we are told that the Park-Hiss type ferments neither maltose nor saccharose while the Flexner variety ferments maltose but not saccharose. The unreliability of such criteria is well shown by the results of Sonné (18), on the influence of the time of incubation on carbohydrate fermentation. He showed that if the fermentation reactions are read in twenty-four hours 42 out of his 74 strains reacted as typically Park-Hiss and the remainder as Flexner, whereas if observed at the end of forty-eight hours the ratios were completely reversed. In addition the fermentation reactions will vary in successive tests at considerable intervals and these fermentation difference may show little correlation with antigenic differences. Such has been the experience of Russon (19), Sonne (18), Kruse (20), Manteuffel (20a), Thomson and Mackie (21), Ledingham (22), Park and Casey (23), Shiga (24), Bauch (25), Gardner (15) and others.

We may then safely conclude that isolation of the bacillus is the only safe method for certain diagnosis of the type of organism causing the infection and that the cultural characteristics have only a very tentative value. The actual nature of the isolated bacillus can only be definitely ascertained by its agglutination by specific sera.

Here again we meet with several sources of error which are in all probability due to variation in the antigenic factors present in the bacilli. For this reason the organisms show a marked difference in their agglutinability with specific sera from strain to strain and from time to time in the strain. Thus we find, for example, an organism which culturally and fermentatively may be considered a member of the dysentery group and yet cannot be agglutinated by specific animal sera. This may be due to one of three factors: 1—Failure to use the specific serum for this variety of organism, 2—Complete or partial temporary inagglutinability, or 3—Actual non-dysenteric nature of the organism which happens to have the cultural and fermentative reactions of the dysentery group. In the first instance, we may remedy matters by using a greater variety of sera so as to include the specific serum for the strain isolated. Real inagglutinability is by no means a rare phenomenon but is usually not permanent and disappears on repeated subculture. These wide variations in sensitivity to specific sera occur both in different races of a single serological group and in the same race at different times. In any case agglutinin absorption methods will almost invariably serve to identify the organism in such instances. The third group has been discussed above and needs no further comment.

(B) The significance of the Agglutination Reaction: As of secondary importance and merely presumptive evidence of the presence of dysentery infection we may mention the agglutination reaction. Here again we have several serious sources of error to contend with. To begin with, positive agglutinations may be obtained with the sera of perfectly healthy individuals where no previous history of dysentery can be obtained. This has caused investigators to establish border line values which however are found to vary from strain to strain and even with a given strain with different authors. Thus the borderline value for B. Flexner has been placed at figures varying from 1/50-1/100 Barrensheen (26) to 1/300 (Egan et al (5)), for B. Shiga 1/20 (Pfuhl (27)), (Jacobwitz (28)) and 1/100 (Egan et al (5)), Schmidt and Umnus (29). This normal agglutinating power has been shown by Burgi (30), not to be attributable to subclinical infections. Healthy sera clump bacilli by virtue of their physico-chemical constitution and independent of any contact with the bacteria in the sense of a previous infection. The intensity of the agglutination varies from species to species and from time to time in the same individual. Above all it varies with the agglutinability of the suspension used for testing the serum. Even in the higher titers one must be extremely cautious in attributing etiologic significance in individual, isolated cases. These positive agglutinations are of diagnostic value only in the presence of significant clinical and cultural support or in cases where definite evidence is presented of contact with a known case of dysentery proven by culture or where the clinical features are very typical.

The difficulty in the interpretation of agglutination reactions is further increased by the frequent occurrence of the phenomenon of cross agglutination. This, to be sure, is more prone to occur with infections caused by *B. Flexner* or the *Hiss-Y* organism but does repeatedly show itself with the other organisms as well and serves to confuse the interpretation of the results. The unreliability of the agglutination reaction is further demonstrated by the occurrence of negative results in cases where the specific organisms may be repeatedly recorded from the stools (Seligman and Cossman (3)). It seems fair therefore to conclude with Flexner that the presence in the blood of agglutinins for dysentery bacilli is of inconclusive value in diagnosis.

(C) Bacteriophagy: Bacteriophagy presents difficulties in interpretation similar to those of the agglutination reaction. From the technical side the use of the plate method to determine lysis is so unsatisfactory and unreliable that results obtained from its use must be dismissed as subject to too great a chance of error. Even with a carefully titrated test tube series of bacteriophage experiments, we usually find so marked a cross lysis with the various dysentery strains that specific interpretation is practically impossible. In addition, we usually find the lytic principle present only during the acute period of the disease as it is beginning to subside so that it is of relatively little value in chronic cases. Furthermore it has been found in "normal," "healthy" individuals further confusing the issue. Thus, Feemster (31) in examining 111 stools none of which were from dysentery patients found bacteriophage present for dysentery organisms in the following proportions: B. Shige, 10 cases; Hiss-Y, 10 cases; B. Flexner, 9 cases; B. Sonne, 6 cases. If one examines the data from thirteen small epidemic outbreaks presented by this author one is struck by the fact that the bacteriophage in itself has no diagnostic value and that even in cases occurring in the course of an epidemic, is of diagnostic value only when a specific organism has been recovered from another case occurring in the same epidemic. These data may be contrasted with those of Winkelstein and Hirschberger (40) who, with a similar but not identical technique, were unable to isolate a bacteriophage from the stools of 45 patients who presented clinical evidence of dysentery.

(D) Incidence and Significance of Chronic Dysentery: The incidence of chronic dysenteric infection has naturally been a matter of great interest and obvi-

ously would have a direct bearing on the problem of the relationship of bacillary dysentery to chronic ulcerative colitis. This of course will depend upon our definition of chronicity and it may be well to take as a border line, an interval of three months from the onset of the original illness. There need not necessarily be continuous clinical manifestations of disease in these cases during the entire period of so called chronicity. However, as can be seen from the above data, recovery of the specific organisms may be successfully accomplished in as high as 80% of these cases, thus indicating their importance as disseminating foci for endemics or epidemics. Using these criteria Froensdorff (43), in a follow up of his war cases of acute bacillary dysentery, was able to find only three chronic cases in a total of 210 (1.43%). Albu (44), on the other hand, on the basis of sigmoidoscopic and clinical observations considers the complete cure and healing of the intestinal mucosa a rare event in bacillary dysentery. Clinically there remains a greater or lesser sensitivity of the colon, which, with a slight stimulus, causes a recurrence of symptoms. In addition he finds sigmoidoscopic changes which persist for years. However, in only two of his cases was he able to recover specific organisms. As a conservative estimate we may take the figures of Leusden (13) who estimated that about 5% of cases of acute bacillary dysentery became chronic. Schurer and Wolff (12) consider that healing of the colon is prevented by the persistence of the original infections. Walko (14), in discussing chronic bacillary dysentery, points out that, in his experience, these cases are practically always infectious, whether merely healthy carriers or chronically ill with persistent or recurrent diarrhea.

(E) Epidemiologic Data: Bacillary dysentery, generally considered a so-called tropical disease with occasional spreads to the temperate zones, is in reality a cosmopolitan disease, endemic practically the year round throughout the entire United States. The data for the State of California have been carefully compiled by Reed (32) for the years 1917 to 1932 and show a wide distribution of the disease through this fifteen year period. An examination of the monthly data on the incidence of dysentery in this country as published in the United States Public Health Reports shows that cases are reported practically each month throughout the year in states from coast to coast. Further investigation of this same source yields the interesting data on the incidence of diarrhea and enteritis for infants under the age of two years as follows:

	Number of cases	*Rate per 100,000*
1931	18,704	15.7
1932	14,375	12.0
1933	15,706	12.5

These data may be compared with the dysentery rate for the same years in adults:

	Rate per 100,000
1931	2.0
1932	1.7
1933	2.2

If, as we feel, we are justified in assuming that the vast majority of the infantile cases were in reality infections with B. Dysenteriae as was shown by Wollstein (33) and Flexner (34), it can be seen how much more frequent are these infections in infancy, at least in these more severe forms, than in adults. This may be contrasted with the relatively infrequent occurrence of chronic ulcerative colitis in the infant age period. Further proof of the endemic nature of these infections is presented by the data presented by Hassler (35) (Leipzig), Silverman (36) (New Orleans), Smyly (7) (Peiping), Smillie (37) (Boston), Thjotta (38) (Norway), Felsen (39) (Jersey City) as well as the data kindly placed at our disposal by Dr. Boldman of the New York City Department of Health which showed the presence of over 500 cases of proven bacillary dysentery in this city during the first ten months of 1935. These occurred in apparently isolated cases as well as in small epidemic outbreaks.

Bacillary dysentery is primarily a human disease widespread throughout the entire world and affecting mankind regardless of age, color, sex, or social status. As indicated above it has a tendency to occur more frequently in infancy and childhood, at least insofar as clinical manifestations are concerned, although no age period is exempt. In our forces overseas, it occurred with almost equal frequency in both the colored and white troops, at times involving practically entire fighting units. On exposure, males and females are equally affected as shown by Hassler (35). In general the disease tends to occur in association with a lack of adequate hygienic facilities and is a disease of filth. Its transmission by food handlers and contaminated water is too well known to require comment. It thus occurs less frequently in the higher social classes where contact infection is less likely to occur.

We thus find ourselves faced with a disease universal in distribution, prone to have a protracted course with a period of potential infectivity commensurate with the duration of the bowel lesions and affecting all age periods, regardless of sex or color but with a tendency to infect infants and young children especially those living in unhygienic surroundings.

COMMENT ON THE RELATIONSHIP OF BACILLARY DYSENTERY TO CHRONIC ULCERATIVE COLITIS

The evidence adduced to prove the etiological relationship between the dysentery group of bacilli and chronic ulcerative colitis consists mainly in the finding of positive blood agglutination reactions for this group of bacilli in cases of chronic ulcerative colitis. Such data have been brought forward by Mackie (9), Thorlakson (11) and Winkelstein and Hirschberger (40). As pointed out above, this by itself cannot be considered as adequate and conclusive proof of the relationship. Bacteriophagy, also employed by these authorities, has similar defects and cannot thus be considered satisfactory, sole evidence of such a direct relationship.

Thus far there have been too few studies carefully performed in accordance with the criteria mentioned above to permit us to evaluate the factor of dysentery infection in chronic ulcerative colitis. Mackie and Gaillard (10) were able to find 18 positive dysentery stool cultures in a series of 83 cases which clinically were considered chronic nonspecific ulcerative colitis. In these 18 positive cultures, there were included 5 strains of organisms which, though presenting typical fermentation reactions, showed no agglutination in the number of specific sera used in the tests. Making the necessary correction in the calculated percentage we find it necessary to reduce this from 22% to 16%. Similar results have been obtained by Winkelstein and Hirschberger (11%) (40). Both of these series consisted of cases which clinically, sigmoidoscopically and roentgenologically were considered to be idiopathic

ulcerative colitis. We may thus draw the conclusion that about 10% to 15% of cases considered clinically to be idiopathic ulcerative colitis rightfully belong to the category of chronic bacillary dysentery. The residual 85% to 90% still remain in the group of the etiologically unknown.

The gross clinical features and course of chronic bacillary dysentery and of non-specific ulcerative colitis resemble each other so closely that differentiation is impossible unless we trace a case to a known and proven epidemic—an unusual event. Similarly the sigmoidoscopic and roentgenologic features are so similar that they cannot serve as reliable methods of differentiation. And finally we find that even on the autopsy table, there are few if any features which serve as adequate criteria for purposes of differential diagnosis.

Despite these close resemblances there are other features which make one suspect that the two conditions are not dependent upon a common etiology. Thus, in contrast to the age distribution of bacillary dysentery as given above, we find a preponderance of cases of non-specific ulcerative colitis in the third and fourth decades with surprisingly few cases in infancy and early childhood. In a series of 392 cases seen in the Mayo Clinic, only 19 occurred between the ages of 2 and 14 years. Another discrepancy is discovered in the sex incidence, in which it is found that the disease occurs about twice as often in women as in men. (Hern (18)). Furthermore, despite the wide spread distribution of epidemic bacillary dysentery throughout the armies on all fronts during the World War, the preponderance of males is at present below the age of forty and mainly in the third decade which did not see service overseas. In addition chronic non-specific ulcerative colitis insofar as it has been reported in the literature is not as prevalent in Central Europe as one would expect from the prevalence of acute epidemic bacillary dysentery during the late war.

Finally, we must contrast the well known lack of infectivity of non-specific ulcerative colitis, for which no authority known to us has ever claimed infective properties, with the equally well known infectivity of cases of chronic bacillary dysentery as pointed out by Walko (14) and Schürer and Wolff (12). Bargen, in the larger series from the Mayo Clinic, was able to find but five instances of familial occurrence while Paulson in the Johns Hopkins Hospital series could uncover only one such instance. It has been our experience that where such cases occur we are much more likely to find a definite etiological agent such as amoebae or dysentery bacilli.

It is our impression that taking the ulcerative colitides as a group there will be found definite etiological agents responsible for a relatively small number and that the larger residual group consists of a heterogeneous conglomeration of conditions with variable etiology. As yet we are aware of no single comprehensive study under controlled conditions as described above, in which any single bacteriological agent has been proved to be the sole etiological factor concerned in the production of this syndrome. Certainly, the data presented as the case for B. Dysenteriae Shiga such a variation in criteria and control study that they as yet cannot be seriously considered as the final solution of the problem.

SUMMARY

We have attempted to summarize and evaluate the data bearing on the relationship of bacillary dysentery to chronic ulcerative colitis. There is presented evidence suggestive of such a relationship which however is not sufficiently complete to be considered more than suggestive. Criteria for the evaluation of relevant data are proposed. The widespread distribution of endemic and epidemic bacillary dysentery is noted—a public health problem of great importance and magnitude. The tendency for acute bacillary dysentery to become chronic is discussed; it points to the necessity of carefully following all acute cases for at least five years in an effort more completely to study the relationship of these diseases to one another.

Flexible Tube Gastroscopy: Technique*

A Preliminary Report

By

JAMES L. BORLAND, M.D.

JACKSONVILLE, FLORIDA

THE purpose of this paper is to present as concisely as possible, the technique of flexible tube gastroscopy, and the difficulties that confront a beginner.

THE INSTRUMENT

There are good descriptions of the instrument in the literature, and a detailed description is not necessary in this paper. There are really three of the Schindler gastroscopes in use. These are generally classified by the angle of vision. The original type had a 60 degree angle of vision, and the instrument had the same diameter throughout. The newer, improved, standard type has an 80 degree angle of vision. The rigid metal portion has been made smaller in diameter than the flexible piece, thus giving more comfort to the mouth, and throat, during the examination. It has a better lens system, it is more flexible, and, owing to the wider angle of vision, one may see more of the stomach wall at any one time, an obvious advantage.

Dr. Schindler is now using an instrument with a 50 degree angle of vision; this has greater magnification, and is of some increased value in gastritis. However, it is evident that the 80 degree instrument will remain the standard.

It should be mentioned that it is inadvisable to use house current and rheostat; a dry cell battery with a voltmeter is ideal, and probably necessary. Thus one may be certain of the same *degree of illumination* with each examination. Eight volts are recommended. The voltage, if lower, does not give sufficient illumination, if higher, may damage the light.

There are several *types of tip*. The original instrument was equipped with a straight tip, as described by Schindler in his original paper. Later, on a suggestion from Henning, the gastroscope was made with a bent tip, either solid, or with a rubber finger. There are certain advantages claimed for this. One, that the introduction through the crico-pharyngeal and cardial constrictions is made easier by taking advantage of the curve, also that the advance down the stomach is simplified by using the bent end to separate the folds. The second possible advantage is in the consequent shortening of the tip, enabling one to insert the instrument deeper. It is certain, however, for one not highly skilled in the introduction of instruments into the oesophagus, that the straight tip is easier, safer, and generally more satisfactory.

We have used two main types of straight tip. The first, the one furnished with the instrument, is tipped with a sponge alone. This is a recent development, also a suggestion of Henning. Its purpose is to clean away mucus ahead of the objective. We have come to the conclusion that this is not necessary, and that the sponge is definitely dangerous. It should be used only in certain rare cases when a centimeter or so of added depth is necessary to visualize the pylorus. The sponge definitely drags in the throat and oesophagus. This is easily felt by the operator's hand, and the drag of the sponge on the mucosa may be strong enough to produce slight tears. Severe sore throats frequently followed the use of this tip, and the sponge was frequently found to be covered by blood streaked mucus. None of these things have been noticed since we shifted to the plain, flexible, rubber finger tip.

One type of tip combined the rubber finger with the sponge, but we feel now that the sponge is in no way useful.

It has been suggested that the tip might well be perforated to allow passage over a thread. The flexible rubber finger removes any necessity for this, except possibly where one wishes to look at the stomach in cases where dilation of the esophagus is present, as in cardiospasm.

CHOOSING THE PATIENT

First, in a general way, the beginner had best choose slim, supple patients that are not only cooperative but intelligent enough to allow them to relax. The procedure is usually easier in women than in men. Negroes, in our experience, are almost uniformly difficult. If the beginner selects the proper patients, his difficulties will be much less.

The *indication for gastroscopy*, is any gastric complaint without absolute contraindication.

The *contra indications* are as follows:

1. Any general condition severe enough to render instrumentation or anaesthetization inadvisable, such as asthma, cardiac failure, toxic infection, etc.

2. Any evidence either from the history or findings, that there is encroachment on the lumen of the esophagus, either intrinsically or extrinsically. Intrinsic lesions so encroaching are stricture, benign or malignant.

Extrinsic lesions that may occlude the lumen are: mediastinal tumor, marked dilation of the aortic arch, aneurysm. The latter is particularly feared.

3. Any evidence that there is dilation of the esophagus. One must particularly look for the localized dilation of diverticulum, either pulsion or traction. Patients with esophageal diverticula or cardiospasm, have been gastroscoped (Schindler), but in the former it is hazardous at best and in the latter should be done only with extreme care, or by passing the instrument over a thread.

4. Failure of an Ewald stomach tube to pass smoothly.

5. Any evidence of esophageal varices, or a disease known to produce these, as cirrhosis of the liver.

6. Not a distinct contraindication, but a possible source of danger are the esophagi which end in

*From the Department of Gastrointestinal Diseases, John Hopkins Hospital.

Read before the August 21 1934

stocking foot deformity. Occasionally the lower end of the esophagus has been seen by X-ray to make a right angle turn before entering the stomach. This angle would tend to be increased by the left lateral position, and although the rubber tip tends to straighten this bend, it seems reasonable to suppose that rough insertion in this type of esophagus, might possibly result in considerable trauma if not in perforation.

The second, third and fourth and possibly the fifth of these contraindications are indications for esophagoscopy.

PRELIMINARY STUDY

Since the gastroscopic examination can be interpreted best in relation to the other findings and is only one part of the examination of the patient, probably all of the other usual methods of arriving at a diagnosis should be done before the actual inspection of the gastric interior. However, the only two necessary preliminary studies are: (a) X-ray of the esophagus, (b) passage of an Ewald stomach tube.

PRELIMINARY TREATMENT

If no obstruction is present, the only preliminary treatment that the patient is given, is one-half grain of luminal three times daily for two or three days, and one-half grain the morning of the procedure. The luminal is given for two purposes: (a) to help relax the patient, (b) to mitigate any cocain reaction.

If obstruction is present, the stomach should be lavaged clean the night before.

For ten or twelve hours before the gastroscopy, the patient receives nothing by mouth except the half grain of luminal with just enough water to swallow the pill. The luminal and water apparently do not produce any appreciable change in the mucosal appearance.

1. The patient is given a preliminary hypodermic injection containing grain 1/6 of morphine and grain 1/150 of atropine. The morphine is not to relieve any pain but to secure relaxation. It has been suggested that by stimulating secretion the morphine may possibly change the mucosal appearance. Dr. Schindler uses only a grain of codeine, and in most cases this should be sufficient. The value of atropine is somewhat dubious. In some cases it apparently increases the spasm at the cardia. Frequently resistance is felt at the cardia when passing the stomach tube after atropinization, when none had been encountered previously. When this occurs, resistance is also met with by the gastroscope.

2. After allowing 45 minutes or an hour to pass, in order to secure the desired action of the medication, the patient is ready for anesthetization of the pharynx.

We began by using the Schindler anesthetization tube with 2% pantocain, containing one drop per c.c. of adrenaline (1-1000). In this method the pharynx is swabbed out with the pantocain. The patient then swallows the small tube until the cross bar is at the teeth, and from 5-6 c.c. of the pantocain solution are injected. Five minutes later this whole procedure is repeated. This is a highly satisfactory method, and has the advantage of securing the patient's cooperation in swallowing, while the pharynx is anaesthetized. The chief disadvantage is that the pantocain is expensive. Schindler states that if the injection of pantocain into the anesthetization tube is forceful, the pantocain emerges as a spray, and none is swallowed. In our experience however, a small amount of the pantocain is usually swallowed. In the event that a reaction should occur, it is possible that the swallowed pantocain might be incompletely removed by the stomach tube, with aggravation of the reaction. Presumably however, pantocain reactions are too rare to justify this objection, and in any case the risk is less than with cocaine.

The usual method of applying cotton swabs, soaked with a few drops of 10% cocain, to the posterior pharynx is a rapid and satisfactory method. The anesthetization is not for prevention of pain but to abolish the gag reflex. Gagging, of course, disturbs steady vision, and air is lost more rapidly than it can be injected.

As soon as the gag reflex is abolished, the stomach is emptied. An Ewald stomach tube of the same diameter as the instrument is used, in order to test the patency of the esophagus. The patient swallows the tube, and then, by leaning down on a tilted table, allows the stomach to empty by gravity. Mucus and fluid, if left in the stomach, will prevent clear vision.

The patient is now shown the position to be assumed, the left lateral decubitus. The left arm must be under the body. This is highly important because it corrects the sag between the dependent side. The knees are well drawn up, the lumbar spine is bowed convex posteriorly. It is well to spend some time in practice, until the patient can assume the proper position, without being pulled or pushed into place.

INSERTION

The patient being in the proper position, the head holder places his left hand under the head and supports the head with his hand, the right hand merely steadying the head. The little finger of the left hand is used to draw down the lower corner of the mouth. The neck must be limp. The head is slightly extended on the neck and is held so that the face is a little in advance of the neck and chest. The head is dropped slightly so that the right angle of the mouth is in line with the esophagus. As the instrument is advanced down the esophagus, the extension in increased as necessary. It must be remembered by the head holder, that this extension is extension of the head on the neck, not the neck on the chest (the latter movement tending to close the esophagus). The neck is maintained in the plane of the body and slightly flexed. The success of the procedure will frequently depend on the above. The patient must be in the proper position, and he must be relatively relaxed. Almost all of the difficulties of insertion are directly traceable to faulty position and stiffness. The patient's tendency is to extend the neck on the trunk, and to arch the back, two things that invariably put the operator in trouble.

The operator now takes the instrument and rests the metal end in an assistant's hand. This assistant must keep the instrument from bending too far, particularly at the vulnerable point, the juncture or rubber and metal. The gastroscope is held perpendicularly to the body. The operator's right hand holds the flexible part, introducing it over the right side of the tongue, and by bending this portion, gently inserts the tip along the posterior pharyngeal wall, until an obstruction is felt (the crico-pharyngeal constriction). The fore-finger of the left hand is used to keep the tip from being bent down and across the lumen, and to keep the instrument up in the right side of the mouth. At this point two procedures may be followed. The

beginner, or one inexperienced in introducing instruments into the esophagus, had best wait until the patient swallows when he can feel that the slight resistance to the tip has disappeared. After the feel of the instrument has been acquired, he may gently pull forward the base of the tongue, and by very gentle pressure insinuate the tip past the cricoid. In either case it cannot be emphasized too much that if there is an open lumen ahead, and the instrument is not caught by the upper teeth, that no resistance is felt. *Do not push, wait!* If the beginner encounters resistance in any way stubborn, he had best withdraw, and try again another day.

After the cricoid is passed the instrument will slip down the esophagus almost of its own accord until the cardiac pinchcock is reached. Here, in many cases, resistance will be re-encountered. Again the operator must maintain very gentle pressure, and wait until the resistance disappears. Sometimes deep breathing will help. After passing the cardia (approximately when the teeth are at the white mark on the instrument) the tip is in the stomach. The next move is the most crucial. The instrument must be inserted as deeply as possible. In most cases it is necessary to advance until the light connection arm is almost at the patient's lip. This is more difficult than it sounds. Spasm will be encountered which sometimes will be almost impossible to overcome. We have noticed under the fluoroscope, persistent spasm, almost cutting the stomach in two parts. More often however, the resistance is really in the mouth, and can be removed by changing the position of the head slightly, pulling the lip away from the instrument, or by opening the patient's mouth a little more. In any case there is no hurry—one had best be gentle and take his time. Schindler's rule, "Quick insertion, without force," establishes an excellent goal to be reached with increasing skill. A rapid insertion will push the tip to the lower part of the stomach before persistent spasm can appear. In addition, rapidity takes advantage of the first relaxation of the cardia, which is brief and almost coincident with the first swallow. This can be demonstrated under the fluoroscope with barium. However, until one has acquired delicacy of touch, swift insertion is dangerous.

When the instrument has been introduced as far as possible, switch the light on, make certain that the voltmeter registers 8 volts, and then by turning the instrument, try to locate the *angulus*, which will be seen as a fold hanging down across the field. Inflate the stomach very slowly and carefully. When the angulus is found, a deep breath by the patient will reveal the *antrum* beyond. One is now in position to locate the *pylorus*. This is accomplished by watchful waiting, and very slight air inflation. It is usually located during a deep inspiration. Too great an inflation will push the pylorus irretrievably from view.

It is advisable to mention one or two points concerning the location of the pylorus. The rugae, seen running on the floor of the antrum, converge at the rosette shaped pylorus and thus may be used as guides. One must be careful not to confuse a peristaltic wave in the antrum with the pylorus. These waves simulate the pylorus as they sweep down over the antrum.

Remember also that although the first portion of the duodenum sweeps posteriorly, in many cases, the terminal portion of the antrum and the pylorus appear to open anteriorly. In the majority of cases the entire antrum can only be seen by watching a peristaltic wave pass to the pylorus.

The remainder of the stomach is seen by slowly turning and withdrawing the instrument, bringing each portion under observation. Sufficient air is injected to push the mucosa away from the lens. Apparently one need not fear over inflation.

There is no need for hurry, one may take all the time required for complete observation. The light lens is never more than warm, no matter how prolonged the examination. The patients are rarely uncomfortable. They occasionally complain of pain in the mouth or throat, which can usually be relieved by changes in the position of the head. If morphine is not used as preliminary medication, the patients feel the movement of the instrument in the stomach. If too much pressure is exerted, this tactile sensation increases to pain, and is felt just to the left of the mid epigastrium. The pain is promptly relieved by relieving the pressure.

Frequently when one first looks into the instrument, nothing can be seen, not even the light; or only half the field is seen. This means faulty position, and a double curve in the flexible portion. Usually if one reassures the patient, asking him to breathe deeply and relax, this is overcome; if not, readjustment of the neck and body may correct the curve. Occasionally no vision can be obtained and the patient must be brought back another day. The second examination is invariably satisfactory.

ORIENTATION

This is the most difficult technical point in the procedure. It is only by practice and patience that one can be sure of just which area of the stomach is under observation. Each operator must discover this for himself. There are several points however, that may help in learning orientation.

The operator had best take a ruler, or a sheet of paper with suitable marks, and practice observing these through the gastroscope. When this is done several things become apparent, which if unknown, will confuse the observer. Chief of these is that the 80 degree angle of vision gives one a much wider view than expected. It becomes apparent that if the stomach wall be 2-3 cm. from the objective, nearly the whole area between lesser and greater curvature will come into view. The corallary to this is the same point may be observed, even though the instrument be turned through a wide angle. It may be observed, also, that the central portion of the picture is magnified more than the periphery, and that this point is helpful in determining when the object is directly under the ocular. Also, a line on the paper (or a fold on the gastric wall) changes direction with rotation of the instrument depending on the direction of rotation. This may also be used in determining at which point the ocular is directed toward the object in question.

Observation of the paper and marks will reveal that the easiest way for the observer to judge direction, is to picture himself looking out of the objective window, keeping in mind that the patient is on his left side. Then what appears to be toward his left, is to his left, and so forth. Thus with the objective directed toward the anterior wall (as shown by the knob on the eyepiece, which corresponds to the objective) what appears to his left is proximal, what is to his right is distal and so on.

In addition to the above there are several things which help maintain general orientation.

First of these are the outstanding landmarks. The *angulus* which is readily recognized as a veil hanging down over the field, indicates that one is looking at the entrance to the antrum. The *musculus sphincter antri*, which appears to be a fold twisted like a rope, forms part of the anterior boundary of the antral entrance. The "mucus lake" indicates the most dependent portion, usually at the junction of the upper and middle third of the stomach. The *fornix* is seen as a deep recess.

Gradual familiarity with the gastroscopic picture also enables one to place himself fairly accurately. There are certain definite characteristics of each portion. These are not within the scope of this paper, but are recognizable with experience.

POST-INSTRUMENTAL TREATMENT

We have had no reactions of any consequence. One of the first patients complained of severe dyspnoea, and pains in the midthorax, but evidently this was hysteria.

In one or two cases, the examination was followed by epigastric pain. This, however, was apparently due to overinflation, since it was relieved by withdrawing air through a small stomach tube.

Approximately half the cases have a sore throat, varying from slight to moderately severe. More careful handling of the instrument in the throat has reduced the number and severity of these.

Routinely, for the remainder of the day, patients are given only cold liquids. This is probably not important.

It is advisable, in order to alleviate the sort throat, that the patients use a hot salt or mild astringent gargle every one or two hours for the remainder of the day. In addition they are given about a half teaspoonful of dry bismuth subnitrate every two to three hours. The bismuth may coat over and protect any small denuded areas in the throat.

CONCLUSIONS

Gastroscopy is a safe, simple, means of observing the gastric interior. It may be used routinely to examine the gastric interior in order to obtain valuable diagnostic information, that can be secured in no other way.

The detailed description of the technic of insertion is given with a few suggestions in the technic of orientation.

Experimental Study with Certain Tips Used on the Wolf-Schindler Flexible Gastroscope*

By

RUDOLF SCHINDLER, M.D.

and

JOHN F. RENSHAW, M.D.

CHICAGO, ILLINOIS

IN the development of gastroscopy it was thought that the construction of a flexible gastroscope would entirely eliminate any dangers arising from the procedure. This proved to be the case until the instrument was modified by the substitution of the sponge tip of Henning for the rubber finger tip previously used on both the rigid and flexible gastroscopes. In several thousand examinations with the flexible gastroscope and rubber finger tip carried out by gastroscopists here and abroad, perforation of the stomach was never observed. In a series of 360 examinations made with the flexible gastroscope and rubber sponge tip we have had three perforations of the stomach, and we know of two others. Hence, we have undertaken a complete investigation of our accidents.

INCIDENCE AND TYPE OF ACCIDENTS

With the rigid gastroscope. Accidents with the rigid gastroscope were reported by Hertel and Kallius (1), Sauerbruch (2), Korbsch (3), Bingel (4), Veillon (5), Schindler (6), Hübner (7), and others. The number of accidents is not known, but it was large. It must be emphasized that all these occurred prior to the invention of the flexible gastroscope in 1932. The lesions were in the esophagus, particularly the lower esophagus. There have been reported only two cases of perforation of the stomach. One (6) was produced by a student who caught the stomach wall between the outer and optical tube of the instrument and caused a tear while withdrawing the gastroscope. Knack (8) observed a perforation of the greater curvature. It is important to note that the danger of the rigid instrument was perforation of the esophagus. In several thousand examinations which have been carried out with the flexible gastroscope *no esophageal lesion has been described.*

With the flexible gastroscope. An investigation of the experience of some other gastroscopists was made. Henning (9), Gutzeit (10), and Moutier (11), each having performed over a thousand gastroscopies with the flexible gastroscope, state that they have had no accidents. Two men (12, 13), however, did report having had accidents. Each had one perforation of

Submitted September 8, 1936.

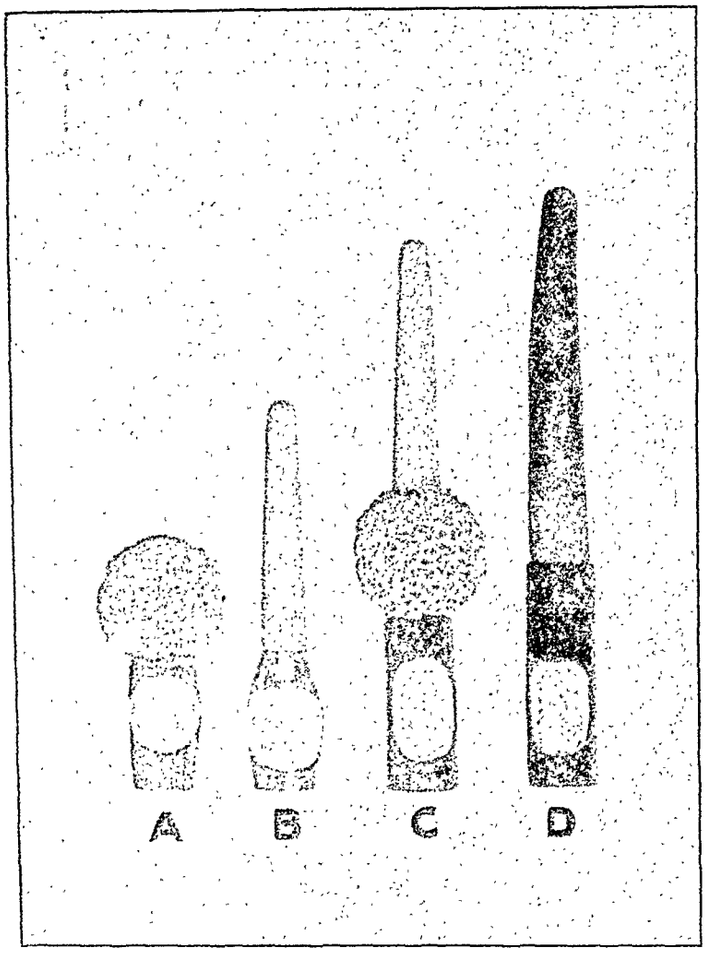

Fig. 1. Types of tips used in this study. (a) is the Henning sponge tip, (b) is the 4 centimeter finger tip, (c) is a combination sponge-finger tip, (d) is a special 6 centimeter tip.

the stomach. In each instance it occurred in a patient with an "apparently normal" stomach and recovery occurred without operation. The diagnosis of perforation was made by the finding of pneumoperitoneum. In an approximate total of 4000 known examinations by the above mentioned gastroscopists there have been but five known accidents. It should be emphasized that none of these accidents involved the esophagus and that *none of them has been fatal.*

POSSIBLE FACTORS INVOLVED

Type of tip. Three types of rubber tips have been used on the flexible gastroscope: the long conical finger (Schindler), the spherical small rubber sponge (Henning), and a combination sponge finger. (Figure 1)

Type and location of lesion. In our cases the gastric lesion proved at operation to be carcinoma. In one case it involved the junction of the upper and middle third of the body producing an hour-glass deformity. The cardia was not involved. In the other two cases a considerable portion of the lesser curvature was involved.

Site of perforation. In all of our cases the perforation was through an uninvolved portion of gastric wall, not through the tumor. Two were high in the posterior wall, and one was in the anterior wall near the greater curvature.

Condition of the gastric wall at the site of perforation. The operative report described the gastric wall of two cases as "definitely more friable than one would consider normal." In Case 3 "it may not have been quite as resistant as the normal wall usually is, but the difference was not marked, and the sutures held as in the normal stomach wall." No sections were made in the first case. The tissue removed from the edge of the perforation in Cases 2 and 3 contained only mucosa and submucosa, which were normal; but we can say nothing of the condition of the muscular layers.

Mechanism of perforation. In two cases the peritoneum was definitely seen. The perforations were due to the tip and not to the distension with air.

CAUSES OF PERFORATION

Were contraindications present? In Case 1 there was a known hour-glass deformity which was not considered a definite contraindication and even now it is not if the proper type of tip is used.

In the second case roentgen examination did not show any carcinomatous involvement of the cardia or esophageal hiatus. The Ewald tube was easily introduced into the stomach. It cannot be said that there

Fig. 3b. Sponge tip in the same stomach. Immediately ahead of the sponge the mucosa is heaped up. The tip is beginning to push out a pouch and stretch the mucosa above it. The instrument is not curved or bent.

were contraindications present in this case. Case 3 was done to check the X-ray diagnosis of a polyp of the cardiac portion of the stomach. It seems that this was a definite indication for gastroscopy and not a contraindication. Again it should be recalled that none of the perforations was through tumorous tissue.

Friability of the gastric wall. The fact that in Case 3 the gastric wall was not definitely friable and the fact that the other reported accidents (12, 13) occurred in normal stomachs argues that friability is not a sole factor in causing perforations.

Elasticity of the instrument. Experience has proved that the present instrument has the proper flexibility to prevent esophageal lesions and still permits excellent visualization of the stomach.

Angle of impingement on posterior wall. The flexible gastroscope strikes the posterior wall at approximately the same angle that the rigid instrument did—about thirty degrees.

The role of the Assistant. In our series all the accidents occurred while an inexperienced assistant was holding the head. An inexperienced assistant may render the examination difficult and unsatisfactory.

The speed of the introduction of the instrument. In our series the perforations occurred, not when the instrument was moving rapidly but when a "slight resistance" was felt and movement was slow. However, the old rigid instruments were frequently introduced slowly, and yet they did not perforate the stomach.

To demonstrate experimentally the effect of the velocity of the instrument we made repeated observations in the following manner:*

A dog stomach was first stretched tightly in the frame and placed at an angle of thirty degrees to the horizontal. The instrument, which was not counterbalanced, was allowed to fall of its own weight from different heights. The results were always the same: both tips slid rapidly over the membrane to the farthest edge, thereby bending the lower part of the gastroscope. Both tips slid easily when the stomach was suspended loosely in the frame, but the sponge tip occasionally stopped before it had gone the full length of the membrane. This sliding may be explained by two facts. First, if the instrument is passed rapidly, the inertia of the stomach wall changes none or little at all before the tip has passed over any particular area. Second, by the time the inertia of the stomach has changed the flexible part of the instrument is well into the stomach, permitting the instrument to bend readily. *The friction between the tip and the gastric wall.* A dog stomach was placed at an angle of thirty degrees with the horizontal. The instrument was exactly counterbalanced. The tip was gently placed in contact with the uppermost part of the membrane. Water was slowly added to a bottle on the carriage. It was run in from a burette with a long rubber tube which extended to the bottom of the bottle so as to avoid any inertia caused by the fall of water. The end result was considered to be the weight of water necessary to cause the tip to slide the full length of the membrane. There was a relatively constant weight which caused the rubber finger to suddenly slide the full length. Once movement was initiated the tip slid easily and rapidly. With the sponge tip, however, it required approximately 100 grams more to initiate sliding which was jerky.

Table I shows the characteristic results using the sponge tip, a combination sponge and finger, a four centimeter long finger, a six centimeter finger, and a short (2.5 centimeter) finger. It is apparent that the sponge tip creates more friction than the rubber finger or even the combination sponge finger. Each test was carried out as quickly as possible to avoid changes in the membrane, elasticity, tension, and moisture.

TABLE I

Finger Tips Gms			Sponge-finger tips	Henning sponge tip
6 cm.	4 cm.	2.5 cm.	Gms.	Gms.

340	345	370	500	530
335	330	405	420	540
340	375	385	440	530
330	340	390	435	515
315	335	360	410	490

Foot Note Description of apparatus. (Figure 2). The apparatus consisted of a metal upright on a baseboard. The upright was slotted to carry a roller attached to the wooden block, which served as a carriage for the gastroscope and could be easily moved up and down. There was a pulley at the top of the upright so that weights could be attached to a cord and exactly counterbalance the gastroscope and the carriage. At the lower end of the upright was a fixed wooden block through which the gastroscope passed. Below this, on the baseboard, was a frame on which the test membrane was placed and which could be fixed at any point at any angle. Dogs' stomachs were used as test membranes. Some were fresh, others were preserved in 30% glycerine in physiological saline at ice-box temperature to keep them soft and pliable

The transmission of pressure. Finally the question of how the tip transmitted the pressure exerted on the gastric wall by the advancing instrument was considered. This time the entire stomach was suspended loosely, so that the gastroscope passed over the posterior wall. The finger tip slipped easily over the mucosa, whereas the sponge tip "skidded" along the

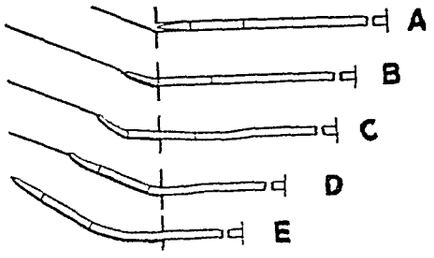

Fig. 4. Diagramatic lateral view of gastroscope as it passes through the esophageal hiatus and along the posterior wall of the stomach. (a) finger tip at the cardia, (b) first contact with the posterior wall, (c) instrument slightly curved from tip through lower portion in esophagus, (d) tip guiding instrument over posterior wall. Note curve of gastroscope, (e) gastroscope advanced to lower depths of the stomach.

surface. Because of the friction between the sponge tip and the stomach the sponge was rolled under itself. The mucosa behind the advancing sponge was stretched tightly, while folds of tissue were piled up in front of it. Many times there was so much tissue piled up in front of the sponge tip that it was impossible to pass over (Figure 3). In these instances the sponge tip pushed out a deep pouch and finally the instrument "buckled," but the tip did not turn upward and slip out of the pouch. When the gastroscope with a finger tip was passed into such stomachs the finger followed down one side of the pouch and curved up the other side until it slipped over the edge (Figure 4).

COMMENT

It is advisable to appraise diagnostic procedures from time to time. Gastroscopists believe that gastroscopy is as safe a procedure as passing an Ewald stomach tube. We are of the same opinion.

It seems that the outstanding factor operative in our accidents was the use of the sponge tip. A rubber finger tip acts as part of the flexible system of the gastroscope. Immediately proximal to the tip is a seven centimeter rigid part consisting of the rubber finger receptor, the lamp, and the objective. Proximal to this part is the main flexible portion of the gastroscope containing the lens system. As the tip protrudes through the esophageal hiatus, the under surface of the finger tip contacts the posterior wall as shown in Figure 4a. As the tip descends a little further, one has the condition represented in Figure 4b. The pressure is increased, but the rubber is pliable enough so that the finger bends easily. As the instrument descends further and more of the finger tip contacts the posterior stomach wall, the resistance or pressure of the stomach increases and the effect of the elasticity of the rubber finger is greater, so that there is a tendency for the upper part of the flexible system to bend very slightly in the lower esophagus (Figure 4c). Finally, the elastic effect is enough to bend the instrument at the junction of the rigid and flexible part as shown in Figure 4d. When the instrument bends at this point, the flexible portion above is slightly curved. The full length of the finger now lies on the stomach wall and slides easily. The finger directs the instrument and initiates an early bending of the upper flexible portion. This results in an increasing surface of contact between the gastroscope and stomach wall as the instrument advances (Figure 4e).

When the sponge tip is used, the first seven centimeters of the instrument are rigid. The vital difference between the sponge and finger tip is apparent. There is no *flexible part* of the instrument in the stomach until seven centimeters have passed the hiatus. There is *nothing* to deflect the sponge tip (Figure 4c). *The entire pressure is always exerted on the very small surface of the stomach wall in contact with the sponge tip.* The tendency is to push out a deep pouch (Figure 4d). The pressure phenomena are exaggerated by the sponge tip because it prevents the instrument from sliding easily. No one will question the fact that an old smooth tire will skid much easier than a new one with a good "non-skid" tread. Likewise, if we used a smooth ball tip instead of a sponge, the former would slide easier than a "non-skid" sponge *but not so easily as a* finger tip which readily adapts itself to any change in contour and follows the course of least resistance. Furthermore, a ball tip would still be objectionable because it cannot direct the instrument nor alter the pressure any better than a sponge tip.

CONCLUSIONS

Evidence is presented to show that the addition of the sponge tip to the Wolf-Schindler flexible gastroscope was a modification which rendered the instrument unsafe. This is in part the result of a "non-skid" effect. The friction between the sponge tip and the stomach wall is greater than with a long rubber finger tip of moderate elasticity and flexibility.

A long rubber finger directs the instrument in the line of least resistance and initiates bending of the flexible portion thereby distributing pressure more evenly. A sponge tip does not deflect the instrument nor does it facilitate its bending and thus the pressure of the advancing gastroscope is localized to a small point beneath the sponge tip.

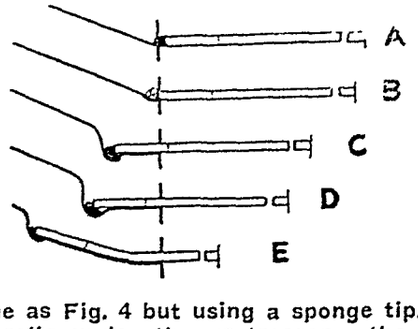

Fig. 5. Same as Fig. 4 but using a sponge tip. Note how the sponge rolls under the gastroscope, the deep pouch that is pushed out, and that the instrument does not bend until the final stage.

We believe that gastroscopy is a safe and harmless procedure if a few simple precautions are observed. Furthermore, we believe it is essential that one use a rubber finger tip four to six centimeters long.

Chronic Hypertrophic Ulcerative Gastritis Treated by Coutard's Method of Roentgen Therapy: Case Report with Unusual Course and Result

By

RUDOLF SCHINDLER, M.D.*
CHICAGO, ILLINOIS

THE following discusses a case of chronic hypertrophic gastritis treated by Coutard's method of protracted high voltage roentgen therapy, demonstrating the results on the chronically inflamed gastric mucosa. The patient was observed over a period of twelve years (1922-1934). During this time he submitted to 65 gastroscopic examinations; 64 of these were performed from 1929 to 1934. The roentgenologic treatment was given in 1932. The gastroscopic observations were made not only by myself but were checked by more than 100 physicians who were participating in gastroscopic courses. Among them were gastroenterologists of world-wide reputation.

CASE REPORT

The patient was a man, born in October, 1875. Since the World War, he had complained of continuous gastric pain which was not relieved by rest in bed, food or alkalies. Because of this pain he applied for a war pension to which he was entitled, according to German law, if disease diminished his ability to work by 30 per cent or more.

Thorough examination in the military hospital of Munich showed no pathologic findings. The patient appeared thin, but the internal organs were normal. Stomach content after Ewald meal contained normal amounts of free and total hydrochloric acid (44 62). No increase of cells was found. Roentgenologic examination of the stomach was entirely negative. There was no occult blood in the stools. It may be assumed that there was no change in these negative findings until the beginning of the Roentgenologic treatment in 1932. Since the military hospital had found that gastroscopy was able to reveal definite pathologic changes in cases in which usual methods had given no results at all, the patient was referred for gastroscopy in 1922.

Gastroscopy was performed with the Schindler rigid gastroscope of 1922. It was not possible to see either the antrum or the pylorus. Only the upper parts of the body of the stomach were observed. These showed very marked changes. The mucous membrane was swollen, velvety, hypertrophic and on the posterior wall three superficial distinct erosions were observed.

The *diagnosis of a marked chronic hypertrophic ulcerative gastritis* was made and the patient received his pension.

He was not examined gastroscopically again until August, 1929. At this time he reported to me that he had never been relieved of his symptoms and that he was completely unable to work. From this time until the invention of the flexible Wolf-Schindler gastroscope, the patient had 16 gastroscopic examinations. The principal findings at each examination were similar. The swollen, velvety, porous character of the mucous membrane of the stomach was exactly the same as in 1922. Only at one examination was it possible to see the antrum and pylorus. The swollen mucosa of the body almost always contained several ulcerations at different sites in the anterior wall, in the greater curvature or in the posterior wall. The erosions were generally yellowish, sometimes white and very shallow. Frequently mucosal hemorrhages, varying in size, were seen.

An unusual feature of this case is that the picture did not show the usual improvements and relapses encountered in this disease, but the condition remained essentially unchanged. The patient said that he was suffering continuously, and he finally received a pension of 100 per cent.

The condition appeared much worse than that of a true gastric ulcer, although in 1932 I had the impression that one of the erosions was so deep, regularly defined and round that the transformation of a gastritic ulceration into a true gastric ulcer seemed evident. However, this was not so. Gastroscopy performed one week later proved that this ulcer had disappeared completely while other superficial erosions had been formed at different sites.

From May, 1932 on, the patient was examined with the flexible Wolf-Schindler gastroscope. With this instrument the antrum and pylorus were always visible. There were also hypertrophic changes, but these were much less marked than in the upper body of the stomach. During this time the patient was treated with rest in bed for many weeks, a bland diet, often merely a liquid diet, hot applications, lavages, intravenous injections of protein bodies, alkalies, charcoal, bismuth, barium, silver, etc. None of these definitely improved the condition.

At that time (1931) Sielmann (Munich) and I had begun to treat selected carcinomas of the stomach with Coutard's method of high voltage X-ray therapy. It is well known that with this type of therapy one tries to destroy tumor cells in the stage of mitosis and finally to kill all cells of the tumor. This therapy causes a very severe "burning" or inflammation of the skin as well as the mucous membrane. When the irradiation is discontinued the in-

*Associate Clinical Professor of Medicine, School of Medicine, University of Chicago; Attending Gastroscopist, the Michael Reese Hospital, Chicago.
Submitted August 17, 1936.

flammation regresses and regeneration of the burnt tissues is observed. The astonishing results need not be discussed in this connection. We had observed this picture not only in cancers of the mouth but also in the gastric mucosa during the treatment of stomach cancers. Therefore I conceived the idea of treating this hopeless case of hypertrophic, ulcerative gastritis in the same way, in order to "burn" the mucous membrane of the stomach and to start its complete regeneration. The patient was told of the uncertainty of this treatment, of the disagreeable incidental effects and of the strain; but since he was suffering from terrific pain constantly he consented without hesitation to undergo the treatment.

Gastroscopy at this time disclosed velvety, swollen mucosa of the whole stomach, numerous very short, extremely stiff folds especially in the anterior wall, numerous small, mucosal hemorrhages and flat yellowish erosions. Two sickle shaped, sharp folds crossing the greater curvature of the body were seen which were again demonstrated in many examinations. Apparently these were caused by fibrous, inflammatory changes of deeper layers of the stomach wall. Some of these changes were photographed with Henning's photographic camera through the rigid gastroscope. The acidity of the stomach contents after Ewald meal was normal. Repeated and very carefully performed X-ray "relief" exposures with controlled pressure failed to demonstrate either the small, stiff folds or the high, sharp folds crossing the greater curvature. These latter two folds were still observed until June, 1934. All Roentgenologic attempts to demonstrate these most outspoken alterations of the mucosal "relief" were in vain.

Coutard's method of high voltage X-ray treatment was performed daily for 45 days. The patient had the usual skin reaction in this type of treatment. He felt very weak but it was not necessary to hospitalize him.

Results of Treatment: Emptying of the stomach before gastroscopy in the second half of the treatment disclosed pus like secretion. Gastroscopically, the mucosa was covered with thick layers of mucus and pus; consequently, nothing could be told from the appearance of the mucosa. Four weeks after the treatment had been discontinued, the mucosa became visible again. Pus and mucus had disappeared completely and at this time, *for the very first time in over ten years a normal mucosa was seen. The velvety swollen character had disappeared completely, the small stiff folds were gone and no ulcerations were present.* The mucosa appeared smooth, glistening, silk-like, similar to that of a healthy individual. Only the two sickle shaped folds crossing the greater curvature recalled the fact that this stomach had been severely diseased.

The patient was free of pain for the first time since the end of the World War. This picture remained unchanged for one year until the end of 1933. At that time, the mucosa above the sickle shaped folds began to look a little grayish. Repeated gastroscopies showed that the grayish area increased in size, the mucous membrane became thinner, and finally in December, 1933, distinct blood vessels were seen. A definite *atrophic gastritis* developed. At the same time the patient began to feel exceedingly nervous. His eldest son stated that living with the father had become very difficult because the father was so irritable. The patient himself complained of irritability, of extreme weakness, of epigastric pressure with gas and eructation. However, this discomfort was not comparable with the former condition of continuous pain.

At this time the observation was interrupted and, since no further data is available, it has seemed advisable to report this most unusual case at this time. A short time ago I received word from this patient that his condition was unchanged.

COMMENT

Chronic, hypertrophic gastritis is a frequent and always severe disease. It is found in about 12 to 13% of all patients who have gastroscopic examinations. From 1922 on, I have seen about 340 cases. Many of these have been followed clinically and gastroscopically for months or years. A complete cure has never been observed in the usual course of the disease, but ulcerations occur only occasionally and in the form of attacks. These heal quickly with a bland diet.

The patient above described is unique because of the obstinancy of the presence of ulcerations which were observed for three years, and which had probably been present for ten years. However—and this fact is remarkable theoretically—none of them developed into chronic gastric ulcers. The severe, painful disease could be diagnosed only gastroscopically. All other methods, especially the X-ray "relief" technic, showed no evidence of the disease. The most marked changes of the mucosal "relief" could not be demonstrated by Roentgenologic examination.

After 10 years of unsuccessful therapy, 45 treatments with Coutard's method of high voltage X-ray therapy were given. The idea was to destroy the diseased mucosa and to cause subsequent regeneration. We succeeded completely with this procedure. After a primary, severe purulent, acute inflammation, the gastric mucosa became normal for the first time in ten years. The patient recovered and remained in good health for one year when atrophic gastritis developed. This form of gastritis is, in my experience, never seen as a result of hypertrophic gastritis. No sign of atrophy was observed in the case under discussion before the beginning of Roentgen therapy. Therefore, we feel sure that this atrophic gastritis was caused by that therapy. Although the usual symptoms of atrophic gastritis developed—nervousness, epigastric pressure, gas and eructation—the condition of the patient was much improved when compared with the extreme pain before the beginning of Roentgen treatment.

Since we were able to observe this patient long enough to witness the development of the atrophic gastritis, we are unable to recommend Coutard's method of high voltage X-ray therapy as a routine measure in this disease. We believe that it should be restricted to the few hopeless cases which have been observed gastroscopically over long periods, in which ulcerations have always been found later and which could not be improved by the usual therapeutic procedures.

SUMMARY

1. A patient suffering from severe hypertrophic ulcerative gastritis was observed over a period of twelve years.

2. The diagnosis could be made only with the use of the gastroscope; X-ray relief technic did not demonstrate the very marked changes of the mucosal relief. Sixty-five gastroscopies were performed.

3. The usual improvement seen in this disease was not observed in this case. Ulceration and extreme pain were present without interruption.

4. In spite of protracted, careful observation, development of a gastritic ulcer into true gastric ulcer was not seen.

5. Coutard's method of high voltage X-ray therapy caused severe, acute, purulent gastritis and subsequent regeneration of an essentially normal mucous membrane. This picture was seen for one year. The patient seemed to be cured when atrophic gastritis developed as a late result of the therapy.

6. Roentgenologic therapy by Coutard's method can be recommended only for the most severe cases of hypertrophic ulcerative gastritis which have been observed gastroscopically over long periods and which fail to respond to the usual methods of therapy (diet, rest in bed, lavage, silver, alkali, etc.).

SECTION II—*Experimental Physiology*

The Proteolytic Effect of Normal Gastric Juice on Beef Muscle Globulin, with Reference to the Reported Action of the Anti-Anemic Intrinsic Factor

By

CHARLES P. EMERSON, Jr., B.S.

and

O. M. HELMER, Ph.D.

INDIANAPOLIS, INDIANA

CASTLE and his coworkers (1, 2, 3, 4) demonstrated that when normal gastric juice and beef muscle were incubated together a substance was produced which was therapeutically active in pernicious anemia. The factor in normal gastric juice he called "intrinsic factor" and the substance upon which it acted he termed "extrinsic factor." He found that the globulin of beef muscle contained the extrinsic factor. Griffiths (5) made a study of the chemical aspects involved in this process, using the beef muscle globulin as a source of the extrinsic factor. This investigator compared the proteolytic effect of normal gastric juice and gastric juice from patients with pernicious anemia —that is, gastric juice presumably devoid of intrinsic factor. This comparison was made on the basis of the production of nitrogenous material not precipitated by trichloracetic acid. There was found to be a small amount of soluble nitrogen produced as a result of incubation at pH 6 which he could not ascribe to the action of pepsin or trypsin and which, on the average, was greater in the case of normal gastric juice than in juice aspirated from persons with pernicious anemia. Griffiths suggested that this production of soluble nitrogen might be related to the action of the intrinsic upon the extrinsic factor.

Using liver extract as a substitute (6), we were unable to demonstrate a change in the nitrogenous components of the liver extract which could be attributed to any other factor than pepsin. Since Griffiths reported a measurable increase in soluable nitrogen when he used beef globulin as a source of the extrinsic factor, we undertook to perform certain experiments based on those described by him, but involving certain additional controls.

Submitted August 11, 1936.

EXPERIMENTAL

Beef muscle globulin, the source of the extrinsic factor in these experiments, prepared according to the method described by Castle (3), was dried in a vacuum desiccator and powdered. Normal gastric juice was obtained (following histamine stimulation) from young, healthy adults, all of whom from clinical experimental work had been shown to secrete gastric juice containing the intrinsic factor. The material thus obtained was filtered clear and kept in a refrigerator until used. Samples containing bile were discarded. The boiled gastric juice employed in control experiments was filtered free of coagulum.

In the first series of experiments the technique employed was similar to that described by Griffiths (5), but with a few modifications. One hundred milligram portions of beef muscle globulin were incubated for three hours at 40° C. with the equivalent of 4 c.c. of gastric juice, boiled and unboiled, at pH 2 (approximate) and pH 6.0. To the incubation mixtures were then added 4 c.c. of 25 per cent trichloracetic acid. Following overnight refrigeration at 0° C. these were filtered clear and the nitrogen content of the filtrate determined.

The incubation mixtures were prepared as follows: To 10 c.c. of gastric juice, boiled and unboiled, possessing a known titratable acidity, were added 10 c.c. of N/10 HCl in the case of the pH 2 mixtures, 10 c.c. of N/10 phosphate buffer in the case of the pH 6 mixtures, an amount of NaOH equivalent to the total acid of the gastric juice in the case of the pH 6 mixtures, and to each was added distilled water in sufficient quantity to bring the volumes to 25 c.c. Of these solutions, 10 c.c. were added to 100 mg. of muscle globulin and 10 c.c. placed in an empty tube for control purposes. One drop of toluene having been added in each case as a preservative, all the tubes, tightly stop-

pered, were placed in a rotary shaker and agitated for 3 hours in a water bath maintained at 40° C.

The nitrogen content of the filtrates was determined according to the manometric method of Van Slyke (7) as modified by Van Slyke and Kugel (8).

CALCULATION OF RESULTS

To determine the true change (C) in soluble nitrogen resulting from incubation at each pH, the value obtained for the globulin incubation mixture containing the boiled gastric juice was subtracted from that containing the unboiled, and from the value (G) thus derived was subtracted the difference in soluble nitrogen (G. J.) between the solutions of the same pH containing the boiled and unboiled gastric juice. The results were calculated on the basis of 100 c.c. of gastric juice.

From the results shown in Table I it appears that in each case incubation at pH 6 led to an increase in the soluble nitrogen of the globulin incubation mixture. The following possible explanations suggest themselves: (1) proteolytic action of the intrinsic upon the extrinsic factor; (2) proteolytic action of pepsin upon the beef muscle protein; and (3) differences in absorption upon the beef muscle globulin of soluble nitrogenous substances in boiled and unboiled gastric juice.

That appreciable peptic action may take place at pH 6 was considered likely in view of the fact that in every case where the rennin content of gastric juice at this pH was determined such activity was demonstrated. In order to test this hypothesis, beef muscle globulin was incubated with pepsin solution (U. S. P. Pepsin 1:3000) at pH 6 under precisely the same conditions employed in the preceding experiments. The concentration of the pepsin solution was adjusted in such a way that its rennin content (determined according to the method employed by Helmer, Fouts, and Zerfas (9)) approximated that of the gastric juice used in the preceding experiments. The results are expressed in Table II and are calculated on the basis of 100 c.c. of pepsin solution.

From the figures shown in Table II it is apparent that at least a part of the increase in soluble nitrogen obtained on incubation of gastric juice and beef muscle globulin at pH 6 may be due to peptic proteolysis. Failure to obtain the same degree of soluble nitrogen change using pepsin solution possibly indicated an independent action on the part of the intrinsic factor of the gastric juice, but we felt that it might also be correlated with the numerous dissimilarities in physical and chemical properties existing between the normal and artificial gastric juices. It was therefore decided to rule out, if possible, peptic activity at pH 6 by employing as a substrate beef muscle globulin which had been predigested with pepsin.

Beef muscle globulin was digested 8 days at 40° C. with one-half its weight of pepsin in N/10 HCl, toluene having been added as a preservative. The solution was then neutralized with NaOH and evaporated by distillation in vacuo, the pH being maintained at approximately 6.5 during the process. The residue was dried in a vacuum desiccator and powdered. An amount of this material equivalent to 100 mg. of the original beef muscle globulin was incubated 3 hours with 10 c.c. of gastric juice solution at pH 6, prepared as described above. Four cubic centimeters of 25 per cent trichloracetic acid were then added and, following overnight refrigeration, the nitrogen content of the filtrate was determined. It was found that boiled gastric juice served as a most unreliable control, since, on boiling, hydrolysis apparently takes place the products of which are adsorbed on the substrate and precipitated by trichloracetic acid to a variable extent. For this reason a control was devised as follows: To an amount of digested beef globulin equivalent to 100 mg. of the original material were added 4 c.c. of trichloracetic acid and then 10 c.c. of the gastric juice solution at pH 6. Following refrigeration, nitrogen was determined on the filtrate. No change in soluble nitrogen occurred as a result of incubation with normal gastric juice at pH 6.

In order to determine the possibility of a proteolytic action not demonstrated by an increase in soluble nitrogen under these conditions, the Willstätter and Waldschmidt-Leitz (10) titration technique was ap-

plied in the following manner. Predigested globulin material was suspended in water in such concentration that 1 c.c. contained the equivalent of 18 mg. of the original beef muscle globulin. Sixteen cubic centimeter portions of this suspension were incubated for 3 hours at pH 2 and pH 6 with 12 c.c. of gastric juice (the acid and alkali required to adjust the pH being contained in 4 c.c. of solution added to the incubation mixture). Following incubation and refrigeration, 1 c.c. samples were titrated in 97 per cent alcoholic suspensions with N/50 NaOH dissolved in 97 per cent alcohol; 5 c.c. samples were titrated in 50 per cent alcoholic suspensions with N/10 NaOH in 50 per cent alcohol. Phenolphthalein (1 c.c. of 1/10 per cent) served as the indicator. Direct color matches between the incubated samples and their controls were obtained. The latter were prepared as follows: The globulin suspension, gastric juice, and pH-adjusting solution were added together at refrigerator temperature, in the same proportion as described above, and 1 c.c. and 5 c.c. aliquot portions of the mixture were immediately pipetted into alcohol. These alcoholic suspensions, containing 97 per cent and 50 per cent alcohol, respectively, were titrated as above. No differences in titration values between the incubated samples and their controls were observed at either pH.

DISCUSSION

The foregoing experiments, using a beef muscle preparation as a source of Castle's extrinsic factor, failed to demonstrate any extra-peptic proteolytic activity in normal gastric juice. It is obvious that these results are not conclusive evidence against the possibility of such activity. For example, the quantitative aspects may be such that the limits of error of the methods employed overshadow the chemical changes sought. So far as the results of the trichloracetic acid precipitation method are concerned, it must be borne in mind that nitrogenous compounds, which alone are not precipitated by trichloracetic acid, may be so precipitated, in part at least, if adsorbed on other proteins present in the mixture. This circumstance appears to account for the fact that occasionally there are marked differences observed between the soluble nitrogen content of boiled and unboiled gastric juice when these are analyzed alone, which are not discoverable when the gastric juices are analyzed in combination with their protein substrates. Such variable behavior on the part of boiled and unboiled gastric juice can render controls uncertain and results dubious.

The experiments involving predigested protein are free from certain of these objections; on the other hand, it is not inconceivable that prolonged incubation of the extrinsic factor with pepsin may lead to its destruction or, at any rate, attenuation. This is considered unlikely in view of the reported stability of the extrinsic factor (11, 12), but it must be considered as a possibility.

The Authors feel that some of the results published by Griffiths may represent physical and chemical processes unrelated to protein hydrolysis, peptic or otherwise. Thus, this investigator reported an increase in soluble nitrogen at pH 2 in the case of gastric juice from patients with pernicious anemia amounting to almost one-third that produced by normal juice, although the data reported by Helmer, Fouts, and Zerfas (9), who studied the gastric secretions of 47 patients with pernicious anemia following histamine stimulation, indicated that the gastric juice contains, on the average, less than 1/100 the normal amount of pepsin.

The disparity between our results and those obtained by Griffiths may be related to the differences between the physical and chemical properties of boiled and unboiled gastric juice mentioned above, which differences would, from a theoretical standpoint, be greater in the case of unfiltered than of filtered gastric juice, and would be especially noteworthy in the case of gastric juice from patients with pernicious anemia, since the mucus content of such gastric juice is very high.

SUMMARY

Efforts have been made to account for the increase in soluble nitrogen obtained by Griffiths on incubating gastric juice containing Castle's intrinsic factor with beef muscle globulin, a source of extrinsic factor.

The results of these experiments fail to support Griffiths' contention that peptic activity at pH 6 can be disregarded, and render doubtful his conclusion that at this pH, proteolytic activity, measurable by the methods employed, is possibly due to the antianemic intrinsic factor of normal gastric juice.

The Changes within the Cells of the Gastric Mucosa During Secretory Activity*

By

ABRAHAM J. GITLITZ, M.D.

and

WILLIAM LEVISON, M.D.

NEW YORK, NEW YORK

THIS study was undertaken in order to correlate the morphological variations of the secretory cells of the gastric glands with stages of functional activity. The detailed analysis of the changes of the known cytoplasmic and nuclear elements will be reserved for a later publication. The discussion is limited to the mitochondria and Golgi apparatus and to the cellular secretory products, such as pepsinogen granules and mucus.

The cycle of events within the cells could be most clearly demonstrated only by active stimulation. In the experiments to be described pilocarpine hydrochloride was employed because of its stimulating action on the mucosa of both the corpus and antrum. The stomachs of the animals studied did not show any pathologic changes and in the longer experiments returned to the phase observed in the controls.

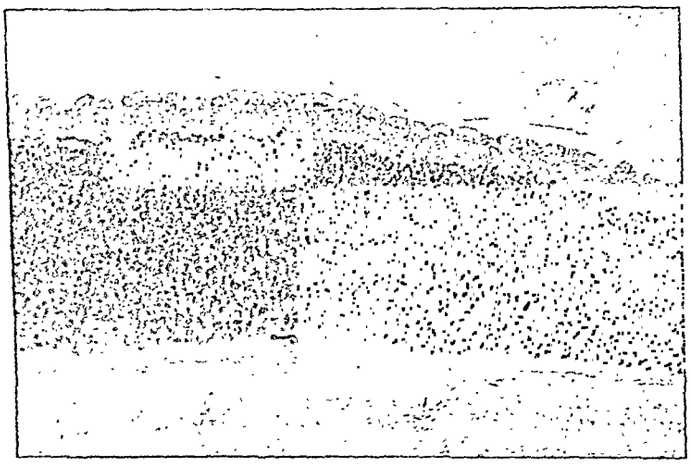

Fig. 1. Fundus. Fed control animal. Uniform character of acid cells. Regaud: Altmann's acid fuchsin. (Low power).

METHOD OF STUDY

Young white rabbits of approximately the same weight were used for the experiments. Four of them belonged to the same litter, three to another. The animals were injected intramuscularly with 12.5 mgs. per kilogram of freshly prepared 1% aqueous solution of pilocarpine hydrochloride. Following this they received no food but were given small amounts of water. Two types of control animals were used. One was fed until the time of the experiment; the other was sacrificed after starvation for 27 hours. The pilocarpine hydrochloride was administered to animals which had been allowed to feed until the time of injection. They were sacrificed at various intervals thereafter. The stomach was immediately removed and the contents collected for acid and pepsin determinations. The tissue was placed into various fixatives for cytological study within twenty minutes after the death of the animals. The major portion of the gastric mucosa was frozen over carbon dioxide ice and extracted for acid and pepsin content.

*From the Laboratories of The Mount Sinai Hospital, New York City. Aided by a grant from Dr. A. A. Berg.
Submitted August 3, 1936.

OBSERVATIONS

In the fundus of the control animal starved for 27 hours the peptic or chief cells of the chief glands are filled with large, round secretory (pepsinogen) granules which occupy the entire cytoplasm and obscure the nucleus. The mitochondria can hardly be identified although short filaments are seen at the base of the cells. The pepsin content of the mucosa determined quantitatively is very high. The cells in the basal portions of the glands are more packed with granules than those in the superficial portions. In the corpus, however, the granules, although numerous, fill only the half of the cell near the lumen. The mitochondria form short, narrow filaments in the basal portions of the cells and extend to the region of the granules. The parietal or acid cells in both the fundus and the corpus contain numerous round granules uniformly distributed throughout the cytoplasm. These granules are smaller than the pepsinogen granules and possess different staining characteristics. The nature of the granules of the acid cells cannot be definitely stated at present.

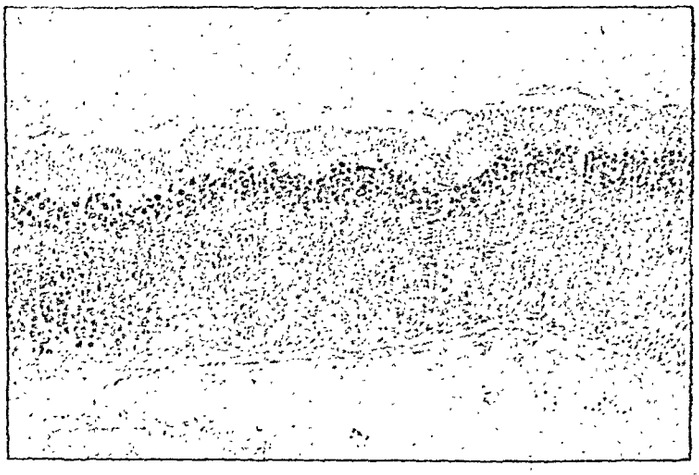

Fig. 2. Fundus. One hour after injection of pilocarpine. Acid cells basal to the neck portions of the chief glands contain less granules. Granules stain less intensely. Regaud: Altmann's acid fuchsin. (Low power).

In the second control animal which was fed until the time of the experiment the peptic cells of the

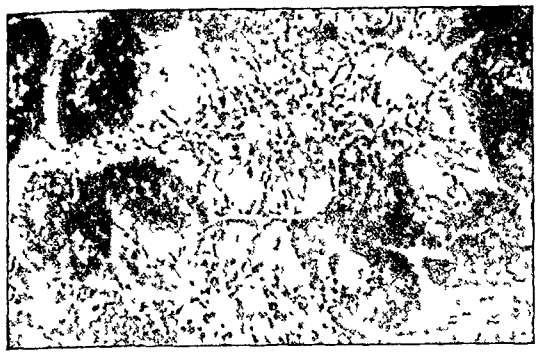

Fig. 3. Corpus. Fed control animal. Peptic cells contain secretory granules near the lumen. Filamentous mitochondria in the basal portions of the cells. Acid cells filled with dark granules. Regaud: Altmann's acid fuchsin. (Oil immersion).

fundus are similar to those in the corpus of the previous animal. The peptic cells of the corpus of this animal contain less secretory granules and more mitochondria. These differences in granule content coincide with the greater digestive activity in this animal. The acid cells are uniformly filled with numerous granules (Fig. 3). Throughout the mucosa the acid cells are similar in character (Fig. 1).

One hour after stimulation with pilocarpine the peptic cells are smaller. There are no secretory granules in the cells except in those in the basal portions of the glands. The mitochondria are scattered irregularly throughout the cytoplasm. The glandular lumina are wider. There is a greater amount of pepsin and acid in the gastric contents. The granules of the acid cells basal to the neck portions of the chief glands are markedly reduced in number, enlarged and stain more faintly so that the unchanged dark neck portions stand in sharp contrast (Fig. 2).

Three hours after the injection of pilocarpine the peptic cells show still fewer granules. There is, however, a small number of large granules in a few cells at the bases of the glands. The mitochondria are short, slender, wavy, more numerous and diffusely distributed throughout the cytoplasm. The pepsin content of the mucosa is markedly decreased; that of the contents is increased. The acid cells basal to the neck portions of the glands contain more granules than in

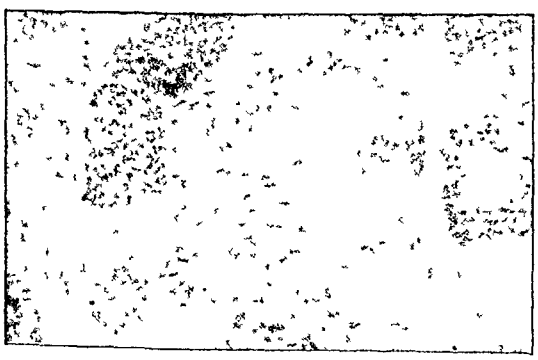

Fig. 4. Corpus. Three hours after injection of pilocarpine. Disappearance of secretory granules from peptic cells. Short mitochondria distributed throughout the cells. Acid cells contain fewer granules. Clear areas around the nucleus. Regaud: Altmann's acid fuchsin. (Oil immersion).

the preceding animal. Clear areas appear in the cytoplasm around the nucleus (Fig. 4). Short, thick rods appear in the central portions of the cells. The acid cells in the most basal portions of the glands are still pale.

Six hours after the injection of pilocarpine the peptic cells are larger. Granules of different sizes appear at the free borders of the cells. This is especially prominent in the basal portions of the mucosa. The mitochondria are longer and for the most part, arranged parallel to the long axis of the cells. They are slender, wavy and often extend from the basal portions of the cells to the region of reappearance of the secretory granules. Many of the mitochondria have eliptical and round bulbous ends. A larger number of acid cells now have central clear peri-nuclear zones. The granules are accumulated concentrically around the border of the cell (Fig. 5). The rods in the central portions of the cells are more elongated and often curved.

Sixteen hours after the injection of pilocarpine secretory granules again fill the superficial portions of the peptic cells The acid and peptic cells closely re-

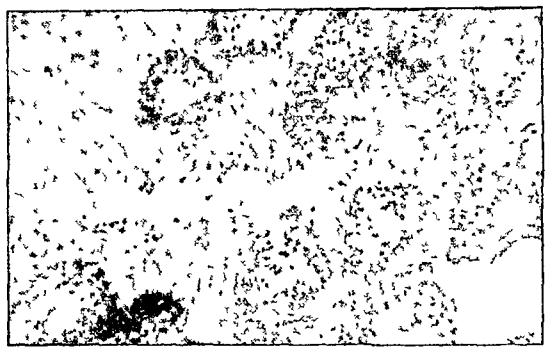

Fig. 5. Corpus. Six hours after injection of pilocarpine. Reappearance of secretory granules at the free borders of the peptic cells. Mitochondria are long, filamentous, and have bulbous extremities. Larger, clear perinuclear spaces in the acid cells. Regaud: Altmann's acid fuchsin. (Oil immersion).

semble those of the fed control animal. The pepsin content of the mucosa rises.

Simultaneously the Golgi apparatus in the peptic cells undergoes distinct variations in form and distribution. In the starved control animal where the peptic cells are packed with secretory granules the Golgi apparatus consists of a small, compact network or small fragments situated near the nucleus on the side toward the lumen. In the fed control where the secretory granules occupy only the superficial portions of the cells the apparatus forms a looser network which is lightly impregnated with osmic acid. It is situated between the nucleus and the free border and extends partially into the region of the secretory granules. With the disappearance of the granules the apparatus becomes more extensive and more darkly impregnated and is situated near the free border of the cell. This process progresses before any secretory granules have reappeared. During the elaboration of the secretory granules the apparatus lies wholly within the region of their formation. As the granules increase in number the apparatus becomes very extensive and appears to consist of impregnated fragments

interspersed among the secretory granules. This state exists until the cells are entirely filled when the apparatus reverts to the resting phase described in the fasting control animal.

A Golgi apparatus has never been clearly demonstrated in the acid cells. Our studies thus far do not permit any definite conclusions.

The action of pilocarpine on the mucus-secreting glands of the antrum is conspicuously depicted in the cytological changes. In the fed control animal the cells contain a large amount of mucus. The Golgi apparatus consists of thin, interlacing strands extending across the entire width of the cells in a zone just above the nucleus (Fig. 6). During all the stages of activity this relationship to the nucleus is maintained. One hour after injection the cells contain only a small amount of mucus near the lumen. The Golgi apparatus is now a dense, large, extensive, heavily impregnated network (Fig. 7). Two hours later the cells already contain more mucus and thereafter continue to store. The Golgi apparatus, however, shows little change until six hours after injection when it decreases in extent and density. In the twelve hour animal the cells are completely filled with mucus. The Golgi apparatus overlies the nucleus and is small and lightly impregnated. It is smaller than the Golgi apparatus in the mucus cells of the fed control animal. The mitochondria do not undergo striking changes.

SUMMARY

A cycle of cyto-physiological changes in the peptic, acid and mucus cells of the gastric mucosa of the rabbit following stimulation by pilocarpine is demonstrated.

SECTION III—*Nutrition*

Vitamin Deficiency in Prescription Diets of Diabetics:†

A Study into the Relationship of Diet Deficiency to Symptomatology as Observed in 85 Diabetics with Previous Dietary Treatment.

By

ANTHONY SINDONI, Jr., M.D.*

PHILADELPHIA, PENNSYLVANIA

THE physician who has made a careful observation of the dietary habits of his patients, in private practice or the clinic, will have obtained sufficient data to infer that disease may result from diet deficiency as well as from bacteria, parasites or toxins. For instance, conditions such as scurvy, rickets, xerophthalmia or night blindness, pellagra, various forms of undescribed dermatosis as well as certain types of anemia, beriberi, peripheral and other forms of neuritis; disorders of the mouth—such as early decay of the teeth, hyperemic, swollen and tender gums—are improved and to a large extent alleviated by the correction of the diet.

In due time we shall have sufficient evidence for the assumption that various endocrine and other unknown pathological disturbances are the result of diet deficiency. McLester (1) states, "Man's place in future history will depend in no small degree on the food he eats——an animal's life processes may be profoundly disrupted by the omission from its food of any one of a number of substances, each of them ridiculously small in the amount required——. In the future it promises to those races who will take advantage of the newer knowledge of nutrition a larger stature, greater vigor, increased longevity and a higher level of cultural attainment. To a measurable degree, man is now master of his own destiny, where once he was subject only to the grim hand of Fate."

The work at present in the field of vitamins is voluminous, as the material published in the various medical journals throughout the world attest. Several vitamins have been isolated and studied both for their chemical and biological properties. The vitamins that have been isolated chemically have been shown to possess vital nutritional factors which are essential for the human body. In our modern world when people are pressed for time they are liable to omit from their diet, in spite of an abundance of food intake, articles of food containing the essential element: *Vitamins.* This is more apparent in classes of people who "fill up" on one or two kinds of food and omit those which help to make a liberal diet. The consequence to our intricate organism is that the normal replacement and requirement of the vast variety of tissues which help to maintain normal metabolism becomes disrupted resulting in various pathological disturbances. An example of such a disturbance was that of a young man coming to our metabolic clinic who developed symptoms and signs of early scurvy evidenced by bleeding and tender gums from a diet consisting chiefly of meat and macaroni. The condition was alleviated by the correction of the diet. To quote E. V. McCollum: "There are at least 37 individual substances essential for a complete diet. These consist of amino-acids (derived from proteins), dextrose, minerals and vitamins. An adequate supply of all these is absolutely essential for life."

There was a time when a physician concentrated his efforts or skill in the treatment of the patient's ailments without much thought to his nutritional state, too interested in the thought that diseases are generally associated with positive agents such as parasites, toxins, the materies morbi = ignoring diet. Today numerous disease deficiencies are recognized, and many others are constantly being discovered. Perhaps many of the inflammatory conditions of unknown origin may be due to dietary deficiency. As Wilder and Wilbur (2) state, "The tendency has been to get away from the treatment of the disease alone and to consider the general nutritive state of the patient." This view, of course, has widened the field of nutrition and caused nutritional disorders to be more easily recognized.

In order to be better able to treat the nutritive state of the individual much should be known of what constitutes a normal, adequate and optimum diet, and what signs or symptoms are produced by its deficiency. Newburgh (3) states, "The physician must decide whether the condition of the patient requires an increase or a decrease, of any one or several of the dietary constituents so that he may modify the normal diet to meet the new requirements." Perhaps in no other field of medicine has the advance of chemistry been more manifest than in the study of vitamins in our natural food. This study has resulted in a more exact knowledge of the composition of natural foods,

*Chief of Diseases of Metabolism, St. Agnes Hospital; Chief Diabetic Consultant, American Oncologic Hospital; Physician to The Medical Dispensary, Presbyterian Hospital, Philadelphia

†Read before the Lancaster City and County Medical Society, Lancaster, Pa., Wednesday, March 4, 1936

Submitted July 18, 1936.

because vitamins have been isolated and identified as chemical substances. This knowledge has done much to aid us in the prevention of disease and the treatment of the sick. Brown (4) calls vitamins, "exogenous hormones" supplied in the diet while hormones are produced in the body. Hopkins (5) emphasizes the fact that one should not separate the functions of the hormones from those of vitamins too widely to appreciate the extent to which chemical substances control and coordinate events in the animal body by virtue of their specific molecular structure. Together they form a large group of substances of which every one exerts upon physiological events its own indispensable chemical influence. McLester (1) claims the preponderance of evidence indicate that the increased growth achieved by well-considered improvement in the diet is accompanied by general physiologic betterment and definite improvement of the species. Also the hastening of maturity may not be of interest to many people, the postponement of senility through betterment of the diet is an alluring thought to every one. Himsworth and Marshall (6) draw the conclusion from diet observations of diabetics prior to onset of the disease that habitual ingestion of a diet containing a diminished proportion of carbohydrate may cause progressive permanent impairment of sugar tolerance and insulin sensitivity so that diabetes mellitus results in the course of time. Mendel (7) emphasizes that diet in every-day life consists of something more than simple mixtures of the commonly recognized foodstuffs such as milk conspicuously represents. Vegetable products, he claims, in the form of leaves, roots, tubers, buds and fruits enter abundantly into the rations of man and of animals. Although unique nutrient advantages are being ascribed to these foods, our knowledge of what actually happens to them chemically in long reaches of the alimentary tract is woefully limited.

Already the medical literature is being crowded with data describing the therapeutic application of the various vitamin concentrate or their equivalent in the treatment of various pathological conditions or states caused by hypovitaminosis or avitaminosis. Wendt (8) describes vitamin A therapy in goiter; Tarr and McNeile (9) claim deficiency of vitamin B in diet of pregnant and lactating women produced pronounced symptoms. Boulin (10) infers from observation that vitamin B exerts a favorable action in certain cases of diabetes so improving the carbohydrate tolerance that the insulin requirement is reduced. This has inspired many with the thought that vitamin B medication could be a substitute for insulin. Drigalski (11) carried on a series of experiments which disproved such substitution. Junghans (12) describes the process of arresting capillary hemorrhages by parenteral administration of vitamin C (cevitamic acid) in gynecologic cases. Quigley (13) made observations in 2707 persons suffering from various types of tumor. He found that all, more or less, were on deficient diets. The correction of the diet alleviated in a large percentage the unpleasant effects of the concurrent diseases and the patients enjoyed better health. Wendt (14) demonstrated that thyroid influences the vitamin A metabolism. Experiments (15) have shown that deprivation of vitamin D insufficient in degree to cause rickets will however produce hypertrophy and hyperplasia of the parathyroid glands. Gierhake (16) verified the work of Evans and Burr that the absence of vitamin E in the diet is followed by sterility, the addition of the vitamin in the diet resulting in the alleviation of the condition. Kerley (17) observed that children on diets deficient in vitamin B were indifferent, lazy and suspectible to infections such as tuberculosis and common colds. In supplying the essential vitamins to children he advises the natural foods in preference to artificial vitamin preparations.

In view of these facts we decided to make a careful study of the dietary habits of a group of patients coming to the Metabolic Department of the St. Agnes Hospital suffering from symptoms other than diabetes. For this purpose we selected the ones who have been under treatment from 3 weeks to 27 years previous to coming to our department. The total number examined were 85 diabetics. The purpose of course was to find what part vitamins played in the patient's symptoms and signs, and the alleviation of these by supplementing the natural foods in the prescribed proportions containing the essential vitamins. This entailed a study into the food habits. Quality and quantity of food eaten were roughly estimated as "small," "medium," "average serving" or "large helpings"; what foods were not desired because of distaste or idiocyncracy; whether meals were eaten regularly or not. This detailed dietary study involved the period prior to the patient's knowledge of the onset of diabetes. Then we inquired into the dietary treatment during the period of the disease. For clarification we may call the former period as the *pre-diabetic,* the latter as the *diabetic.* In the diabetic period we inquired what foods were prohibited and permitted by their family physician in the course of their treatment. Then we studied the symptomology, its duration as also the diabetic disturbances; insulin therapy, its duration and the total dosage for the day as also the age, weight changes, blood chemistry and complications.

RESULTS OF OBSERVATIONS

In the pre-diabetic period we found that 20 or (23%) of the group did not desire fruits, 49 or (56%) never cared for or gave a thought to drinking milk, 12 or (13%) did not care for vegetables; 15 or (17%) specified particular vegetables they did not desire and ate little vegetable with an effort, 34 or (40%) ate pastry, candy or plain sugar, 39 or (45%) were great bread eaters, 32% were overeaters and all ate their meals irregularly. The age variations were from 11 to 77 years.

Table I is a tabulated list of foods which were denied the patients during their *diabetic period.* To this list we inserted their vitamin contents. We have also found this list to be rich in such mineral elements as calcium, sodium and potassium salts, iron, copper and manganese which play a vital part in the structure and function of the body particularly the bones, teeth, soft tissues, and body fluids. Such elements enter into various bodily functions without any planning on our part and for such reasons we did not insert the mineral contents of the various foods. Patients

who avoided the various foods in the list gave as reasons that they were advised because they contained "sugar," or produced "acid" in the system.

The symbols (18) indicate the vitamin content (18, 19, 21, 21) of the foods:

food, everything else which we eat was "intended" by nature for some other purpose. Vegetables are also rich in minerals and vitamins, many of which were also denied the patient. Cereals which are good sources of vitamin B and G factors, which control skin and

? signifies doubt as to vitamin value.
. signifies evidence lacking or appears insufficient.

Mild, bread and *other foods* are now enriched with vitamin D by irradiation processes or by the addition of concentrates of natural vitamin D; egg yolks, clams, oysters, as also fish liver oils which are rich in vitamin A, contain rich source of vitamin D.

Fruits of all kinds were prohibited in the diabetic treatment. As we know, fruits are one of life's protective foods, being rich in mineral elements and in vitamins; we well know that oranges and lemons are excellent sources of vitamin C, protector against scurvy. Milk, according to Sherman, is the only article of diet whose sole function in nature is to serve as

gastro-intestinal disorders, were also denied of the patients (Table II).

Thirty-one per cent of the patients were prescribed special diabetic preparations as gluten bread, diabetic muffins, etc. Is it a wonder the patients broke their dietary instructions with such artificial and restricted diet? *Typical of such restriction is that of a diabetic patient, aged 67 years, under a doctor's care for diabetes, 3 weeks, who recently came to our Metabolic Clinic with the complaint of extreme weakness, vertigo, and rapid loss of weight. He stated he was denied not* only *milk, fruits* but also water. It was impossible for him to adhere to such a diet and he had to break the

doctor's rules to satisfy his instinctive nutritional desires. All this because the doctor found a trace of sugar in his urine, in spite of the fact his fasting blood sugar was 147 mg./100 c.c. when he first entered our clinic.

The fact that most of our biological results are obtained from animal experiments, aids us in recognizing clinical disorders. It has been proved that vitamins are chemical substances present in minute quantities in natural foods upon which the normal function and development of the body depend, and they are essential to life. Deficiency or absence of food containing vitamin A results in disorders of the epidermis, eye, gastro-intestinal and genito-urinary tracts and lowering of resistance to infection. The conditions are improved or alleviated by supplementing the diet with food containing the vitamin. The value of many of these changes has been substantiated in man by various clinical investigators. The lack of vitamin B produces loss of gastro-intestinal tonicity, loss of weight, weakness and lack of vigor. McCollum (22) is of the opinion that vitamin B is essential for perfect nutrition of the nervous system and should be a part of the diet of patients with ulcers. That a neurotic element is a predisposing factor in the etiology of ulcer is accepted by many gastro-enterologists. Its relationship to beriberi needs no further comment as it is well known. Various investigators have sufficient evidence that many people are lacking in amount of vitamin C or ascorbic acid optimum for health. The lack of this vitamin produces scurvy and fragility of the capillaries. Experimental studies have shown that apical abscess from devitalized tooth may be caused by deficiency of vitamin C. Harris and Ray (23) have shown that infants suffering from manifested scurvy excrete less vitamin C in their urine than do well-nourished infants of the same age on controlled diets low in vitamin C. After cure the scorbutic infant behaved like a normal infant. It is well established that lack of vitamin D produces rickets and, in no small degree, suspectibility to respiratory infections as well as to dental caries. Goldberger and his associates (24) have done extensive research in vitamin G (B_2) deficiency associated with pellagra and possible other skin disorders. The correlation of vitamin E with sterility by Evans (25) have shown encouraging results.

In the following *summary the symptoms* were taken on the initial visit of the patients who were denied the vitamin rich foods in the diabetic period. We tried not to include diabetic symptoms.

Head: Tenderness and pain to touch "all over" head, at times marked; sharp and "achy" pains in frontal, maxillary and ethmoid sinus regions; *headache*, frontal, occipital, temporal and parietal areas.
